4                                     **ABSTRACT**

5     Construction companies’ wrongdoings can result in severe consequences and have been a  
6     concern for regulators, investors, and other stakeholders. Though previous studies have  
7     identified a great number of factors associated with corporate misconduct, ranking their  
8     importance and using them to predict this misconduct in the construction industry have been  
9     overlooked. This study developed a random forest (RF) model using data on 873 observations  
10    from 97 China construction companies in 2000-2017. Based on the variable importance  
11    analysis of RF, the top 10 variables were obtained and variables indicating both corporate  
12    governance and financial performance may be associated with an increased risk of corporate  
13    illegal activities. Then RF was compared with support vector machine (SVM) and the results  
14    indicate that both are suitable for predicting corporate misconduct in the construction industry.  
15    These findings expand the study of corporate misconduct in the construction industry and can  
16    be used to guide regulatory decision-making for conducting investigations into possible  
17    corporate misconduct.

## 19 **Introduction**

20 Each year, dozens of deadly construction accidents occur worldwide. Many of these incidents  
21 are attributed to the large issue of corporate corruption. Corrupt practices have damaging  
22 consequences across multiple levels of the construction industry. For the local community,  
23 unemployment may rise, especially when the demand for related secondary business such as  
24 restaurants and gas stations decreases (Zahra et al. 2005). For society, the public's faith in senior  
25 managers and the ability of an executive board to monitor management is shaken (Zahra et al.  
26 2005), with even confidence in the free market system eroded (Paruchuri and Misangyi 2015).  
27 This may cause a depressed moral climate in a society (Shadnam and Lawrence 2011). Apart  
28 from these repercussions, misconduct in the construction industry can lead to injuries and death.  
29 11 workers were killed and 2 seriously injured after the collapse of an elevator at a Chinese  
30 construction site in April 2019 (Xinhua 2019).

31 Preventing such events is a top priority among practitioners and academics. A growing  
32 body of studies (Le et al. 2014; Liu et al. 2017; Owusu et al. 2019) have focused on identifying  
33 causal factors of corruption and generated numerous noteworthy factors. However, due to the  
34 limited budget and resources of a firm, coping with all those factors is very difficult. Even  
35 though a great deal of effort has been put into misconduct prevention practices and research,  
36 corporate scandals continue to arise. Therefore, it is essential to identify and rank the  
37 importance of possible factors. By focusing on the most important factors, investors, regulators,  
38 and other stakeholders could improve the effectiveness of misconduct detection and other

39 critical evaluations.

40           Though recognizing those important risk factors could assist in mitigating corporate  
41 misbehaviors, timely and accurate detection of corporate illegal behaviors is also essential.  
42 However, accurately detecting corporate misconduct is a serious challenge. Some studies (Ngai  
43 et al. 2011; West and Bhattacharya 2016) claim that data mining approaches may be useful for  
44 detecting small anomalies because such approaches can extract and identify relevant  
45 information otherwise hidden in large volumes of data. Support vector machine (SVM) and  
46 other machine learning tools have been employed in analysis of construction cost, injury,  
47 contractor default, and other areas of the construction industry (Cao et al. 2014; Movahedian  
48 Attar et al. 2013; Tixier et al. 2016). The use of these tools, however, remains limited in the  
49 domain of construction corporate misconduct prediction. Wang et al. (2018) developed an SVM  
50 model to predict the occurrence of corporate misconduct in Taiwan based on several variables  
51 related to the board of directors. The study explored the role of statistically insignificant  
52 variables by comparing models with and without those variables, while also failing to provide  
53 a ranking of all variables, let alone the significant ones. In particular, when the number of factors  
54 is large, manual comparison would be time-consuming and inefficient. The present study draws  
55 upon a large quantity of data related to corporate governance and financial performance to rank  
56 feature importance and construct a data mining-based prediction model. By identifying the most  
57 influential factors, the prediction model is expected to provide regulators, investors and  
58 securities agencies with an effective and early misconduct detection tool.

59 **Literature Review**

60 *Corporate Misconduct in the Construction Industry*

61 Corporate misconduct is defined as the actions taken by companies to operate them illegally  
62 when they consider that the benefits outweigh the risks of doing so (Mishina et al. 2010). In the  
63 construction industry, various forms of misconduct have been identified, such as bid cutting  
64 (May et al. 2001), collusive tendering (Dorée 2004; Zarkada-Fraser and Skitmore 2000), and  
65 establishing front/shell companies (Chan and Owusu 2017). These behaviors may be attributed  
66 to underlying factors that are in play at different levels. From a macro perspective, flawed  
67 regulation systems may elevate the chances of opportunistic behaviors, and a negative industrial  
68 climate may encourage bad practices (Le et al. 2014). From a micro perspective, some scholars  
69 emphasize individual traits, like conducive attitude toward corruption (Brown and Loosemore  
70 2015), egoism, and utilitarianism (Fan and Fox 2009). From the meso level, economic pressures  
71 (Alutu and Udhawuve 2009), board structure (Lee et al. 2018), organizational climate (Liu et  
72 al. 2017), commitment of code (Ameyaw et al. 2017), and other organizational factors may  
73 contribute to the occurrence of corporate misconduct. This study builds on the foundation of  
74 these organizational studies.

75         Although many factors have been identified as affecting the likelihood of corporate  
76 misconduct, less research considers ranking the importance of those factors and employing  
77 them to perform corporate misconduct prediction. Moreover, those studies investigating  
78 influencing factors relied on questionnaires, interviews, and other field survey tools to collect  
79 data. That is, the data sets are difficult to access by other researchers and the relationship

80 between those underlying factors and corporate misconduct may not be verifiable. To address  
81 this gap, this study draws upon public information, especially from corporate annual reports, to  
82 serve as a proxy for organizational factors.

### 83 ***Random Forest***

84 RF models have been used in various fields of science and engineering, including the  
85 construction industry. For instance, Tixier et al. (2016) developed a model to predict  
86 construction injury based on RF and Stochastic Gradient Tree Boosting with a set of features  
87 and safety outcomes extracted from textual injury reports. Liu et al. (2018) explored the impacts  
88 of outdoor ambient environment on scaffolding construction productivity via RF and a  
89 generalized additive model. Poh et al. (2018) presented an RF tool to explore safety leading  
90 indicators. Following this line of research, this study applies RF to corporate misconduct factor  
91 identification and prediction in the construction industry.

92         Random forest is an ensemble of small trees trained on a randomly selected sub-sample  
93 of a dataset through bootstrap aggregating or bagging (Breiman 1996). Each tree is trained  
94 through recursive partitioning of features to a certain level of depth,  $d$ . During this process, the  
95 randomly selected observations at each node are partitioned into subgroups to make a prediction  
96 (Breiman 2001). The exact partitioning position and the selection of features rely heavily on  
97 the distribution of observations (Strobl et al. 2009). The features, partitioning by which provides  
98 the most information regarding the observations, are chosen for this process. Several criteria  
99 are used for partitioning, but the most frequent ones are Gini Index (Breiman et al. 1984) for  
100 classification.

101 For each tree  $T_i$  ( $i = 1, 2, \dots, n_{tree}$ ), a new training data set  $S_i$  is generated by  
102 randomly resampling the original training data set  $S = \{(x_i, y_i), i = 1, 2, \dots, n\}, (X, Y) \in$   
103  $R^k \times R$ . Although these sub-samples are different from each other, they must have similar  
104 distribution. Then tree  $T_i$  is created with the set  $S_i$ , by the above mentioned methodology and  
105 without pruning. In this process, some data will be used repeatedly while others might be “left  
106 out” and considered as out-of-bag (OOB) samples. This OOB data is used to evaluate the  
107 internal performance of each tree and to determine the variable importance (Breiman 2001). To  
108 increase the diversity of these trees further,  $m_{try}$  input variables are randomly selected from  
109 the  $k$  variables. Considering the  $m_{try}$  input variables and their linear combinations, a tree  
110 grows by searching the best split based on the generated training dataset and random variable  
111 set. In the same way, all the  $n_{tree}$  trees are constructed and trained. They are expected to be  
112 independent from each other because of the randomization of training data and input variables.  
113 Finally, all the constructed trees are collected into the RF model and vote for the outcomes.

114 For the sample  $x_t$ ,  $f(x_t) = \text{majority vote}\{T_i(x_t)\}_{i=1}^{n_{tree}}$  (1)

### 115 ***Corporate Misconduct Prediction***

116 Though corporate misconduct prediction is not prevalent in the construction industry, some  
117 scholars have attempted similar prediction in the field of organizational management.  
118 Ravisankar et al. (2011) used a multilayer feed forward neural network, SVM, genetic  
119 programming, a group method of data handling, logistic regression (LR), and a probabilistic  
120 neural network to recognize fraud and non-fraud companies with 18 financial items. Pai et al.  
121 (2011) constructed an SVM-based fraud warning model to detect top management fraud based  
122 on 16 financial features about a firm’s profitability, leverage, liquidity, and efficiency, as well

123 as 2 variables about director shareholding. Lin et al. (2015) compared the performance of  
124 several data mining techniques (LR, DT, and Artificial Neural Networks) used as financial fraud  
125 detection tools with experts' judgments to analyze their differences. Most of the variables used  
126 were relevant to financial/accounting performance and several were relevant to corporate  
127 governance. Kim et al. (2016) established three multi-class prediction models using  
128 multinomial LR, SVM, and Bayesian networks. These models drew upon 49 variables,  
129 including off-balance sheet variables, nonfinancial measures, market variables and governance  
130 measures. Dong et al. (2018) adopted LR, SVM, DT, and neural networks and leveraged 3  
131 categories of financial ratios and language-based features for financial misstatement detection.

132         Regarding input variables, most previous research employed financial/accounting  
133 variables. This may be related to the reasons for engaging in corporate misconduct. Unusual  
134 financial ratio values may represent a need to hide losses, to improve apparent stock market  
135 performance, and to satisfy investors, and lenders so as to mitigate managerial pressure  
136 (Ravisankar et al. 2011). Therefore, poor financial performance could be an incentive to commit  
137 corporate fraud. Fraud has been found to be conducted more often by top management (Zahra  
138 et al. 2005). As the chief decision makers, executives have the responsibility for setting the  
139 overall direction of an organization (Hambrick and Mason 1984). Once they decide how to  
140 behave, corresponding proper or improper actions within the firm follow. Thus, an array of  
141 studies attribute corporate fraudulent behaviors to the characteristics of top management  
142 (Schnatterly et al. 2018; Shi et al. 2016; Troy et al. 2011). In an effort to reduce such behaviors  
143 by executives, a board of directors is appointed by a firm's owners to serve as a monitoring

144 device (Fama and Jensen 1983). A board of directors can play an important role in supervising  
145 and guarding against opportunistic behaviors by top management. The effectiveness of this  
146 function is associated with board size, board independence, and other board properties (Lee et  
147 al. 2018; Raheja 2005). Taken together, this may be why some studies (e.g., Kim et al. 2016;  
148 Pai et al. 2011) add several corporate governance related variables (e.g., CEO bonus and board  
149 shareholding) as input features. We followed the above studies and included variables about  
150 corporate governance and financial/accounting variables as our input features. Then, we ranked  
151 their importance, a step not typically considered in previous research, to identify the most  
152 influential factors of corporate misconduct in the construction industry.

153         As for classification techniques, previous studies have often used LR, SVM, and DT to  
154 develop their financial statement fraud detection models. Among them, LR is typically used as  
155 a benchmark (Ngai et al. 2011; Tserng et al. 2011). Though LR is easy to implement, it has  
156 difficulty in handling complex issues, especially fraud detection (West and Bhattacharya 2016).  
157 SVM is one of the most popular machine learning tools. It transforms the original data into a  
158 high dimensional space by nonlinear mapping and separates the data with a hyperplane.  
159 However, SVM is prone to overfitting (Pai et al. 2011). More importantly, SVM lacks variable  
160 importance ranking. With its ability to predict and provide variable importance, DT is an easy-  
161 to-use predictive model that generates mapping from observations to possible consequences  
162 (Ngai et al. 2011). It is constructed as a tree-like structure with attributes as branches and  
163 outcomes as leaves. When developing a predictive model, DT has no requirement for prior  
164 domain knowledge, making its implementation simple (Dutta et al. 2017). However, DT may

165 be unstable and risks overfitting if a single tree is used (Bhattacharyya et al. 2011).

166 To overcome this drawback of DT, random forests (RF) was introduced by Breiman  
167 (2001). As an ensembled tool, RF is composed of a set of trees generated by a classification  
168 and regression tree (CART) (Breiman et al. 1984) and a combination of randomly chosen  
169 explanatory factors. This method inherits several advantages of DT (Sutton 2005). First, RF is  
170 able to handle complex nonlinear high-order interactions among features and does not require  
171 feature selection. It is also robust even with outliers and irrelevant inputs, as well as able to  
172 avoid overfitting (Rodriguez-Galiano et al. 2012). Next, there is no requirement for prior  
173 knowledge of underlying processes and no assumptions about the target function (Prinzie and  
174 Van den Poel 2008). RF has been shown to be among the most accurate general-purpose tools  
175 to date (Biau 2012). It additionally provides useful estimates of variable importance (Breiman  
176 2001). With identifying variable importance and establishing an accurate prediction model as  
177 the primary aims of this study, RF is thus applied to the factor identification and prediction of  
178 corporate misconduct in the construction industry.

## 179 **Method**

### 180 *Variable Importance*

181 One of the most desirable characteristics of RF is its ability to generate variable importance. To  
182 compute the importance of a variable, RF first randomly permutes the value of a variable and  
183 keeps the others unchanged. Then a set of new trees is established. A set of accuracies  
184 corresponding to the modified OOB data is generated and compared with accuracies  
185 corresponding to the original OOB data with all of the variables. Their differences are

186 calculated and averaged. The average value indicates the importance of that permuted variable.  
187 The larger the absolute value of the average of the differences is, the more important that  
188 variable is. The underlying rationale is that the data permutation of a variable would break its  
189 association with the output, and as a result, there would be a decrease in the accuracy if the  
190 permuted data were used as an input (Strobl et al. 2009). That is, if there is indeed a relationship  
191 between a variable and the output, replacing the original data with the permuted data would  
192 lead to a significant decrease in the accuracy, otherwise the replacement would make no  
193 difference to the accuracy. By doing so, RF reveals the variable importance and the association  
194 with the output. In particular, this association takes into consideration interactions with other  
195 variables (Strobl et al. 2009; Tsanas and Xifara 2012). The redundant variables are not given a  
196 priority even if they have a high correlation with the output. This function of RF facilitates  
197 research with high-dimensional data as is the case with the present study analyzing dozens of  
198 variables about financial performance and corporate governance.

### 199 *Evaluation Metrics*

200 Some studies (Bhattacharyya et al. 2011; Hajek and Henriques 2017) claim the cost of  
201 misidentifying lawful corporate behaviors as wrongful is much higher than that of neglecting  
202 to identify wrongful behaviors. This present study proposes that the cost of incorrectly  
203 classifying a lawful company as a violating one should not be overlooked as well. When a  
204 company is considered violating, subsequent investigation can be undertaken. If such actions  
205 are wasted on a lawful company, a fraudulent company would remain at large because of the  
206 limited resources of regulators. Moreover, investors would prefer to identify a trustworthy firm

207 than a questionable one to achieve profits from their investments. Therefore, this study attempts  
208 to assess the performance of RF on both violating and lawful observations.

209 Whether the evaluated company is violating or lawful, the metrics used in this study  
210 are calculated mainly on the basis of the confusion matrix shown in Fig. 1.

211 -----  
212 Insert Figure 1 about here.  
213 -----

214 If the aim is to evaluate the performance of RF on violating observations, the violating  
215 companies are considered as positive while the lawful ones would be negative. Then TP is the  
216 number of violating observations classified correctly as violating. FN is the number of violating  
217 observations classified incorrectly as lawful. FP is the number of lawful companies falsely  
218 classified as violating while TN is the number of lawful companies accurately classified as  
219 lawful. On the other hand, if the aim is to evaluate the performance of RF on lawful companies,  
220 then the lawful companies are considered as positive while the violating one would be negative.  
221 TP and FN are the number of lawful observations correctly classified as lawful and wrongly  
222 classified as violating, respectively. FP and TN are the number of violating companies  
223 incorrectly classified as lawful and rightly classified as violating, respectively.

224 Based on the above confusion matrix, the metrics applied in this study include accuracy,  
225 precision, recall, and F1-score. These metrics can be formulated as follows:

226  $Accuracy = \frac{TP+TN}{P+N}$  (1)

227  $Precision = \frac{TP}{TP+FP}$  (2)

228  $Recall = \frac{TP}{P}$  (3)

229  $F1 - score = 2 \times \frac{Precision \times Recall}{Precision + Recall}$  (4)

230 *Sample and Data*

231 Our samples consist of all the publicly traded construction companies listed on the Shenzhen  
232 Stock Exchange and Shanghai Stock Exchange in China. All of these companies' information  
233 is derived from the China Stock Market and Accounting Research (CSMAR) database. This  
234 database collects financial and governance data mainly from the companies' annual, semi-  
235 annual, and quarterly reports. Some governance data is complemented by interim  
236 announcements by the board of directors, board of supervisors, and shareholder meetings.  
237 Regarding violation information, a list of violating companies was extracted from enforcement  
238 information published by the China Securities and Regulatory Commission (CSRC). By  
239 examining the violating cases carefully, this study identifies the year when violating behaviors  
240 are actually taken. If an illegal activity lasts for several years, we treat the company as a violator  
241 each year on the assumption that the activity could have been stopped at any time. If the date  
242 when a firm participated in fraud is not mentioned in the violating cases, it is assumed that the  
243 violation was detected immediately after the action took place. Though the CSMAR database  
244 collects enforcement information from 1994 to date, most records about construction  
245 companies begin after 2000. Thus, this study focuses on 97 construction companies over the  
246 period 2000-2017 to capture as much available data as possible. After data points with missing  
247 values were excluded, 873 final observations are yielded. Among them, 155 observations  
248 engaged in misconduct have been reported.

249 *Measurement*

250 As the output, corporate misconduct is operationalized by a dummy variable indicating whether

251 an observation engaged in corporate misconduct or not. If yes, the observation is considered as  
252 violating and its label equals 1. Otherwise the observation is considered as lawful and its label  
253 is 0. This study employed 61 variables as the input, shown in Table 1. Among them, 24 were  
254 about corporate governance and the remaining were financial variables. These variables were  
255 selected because they encompass a wide cross-section of corporate governance information and  
256 financial ratios. Governance variables (X0-X23) show the structure, compensation, and other  
257 related information about the board and TMT. They have been reported to be related to illegal  
258 corporate behaviors (Chen et al. 2006; Dechow et al. 1996; Harris 2008; Jia et al. 2009; Kesner  
259 et al. 1986; Lee et al. 2018; Schnatterly et al. 2018; Sen 2007; Wowak et al. 2015; Zahra et al.  
260 2005). Financial ratios included several financial aspects of the construction companies, i.e.,  
261 structure ratios (X24-X28), liquidity ratio (X29-X36), growth capability (X37), operating  
262 capacity (X38-X46), per share indexes (X47-49), and profitability capacity (X50-X60). The  
263 financial variables were adopted mainly based on previous studies on fraudulent statement  
264 detection (Dutta et al. 2017; Hajek and Henriques 2017; Kim et al. 2016; Kirkos et al. 2007;  
265 Lin et al. 2015; Pai et al. 2011; Perols 2011; Ravisankar et al. 2011). Their calculation was  
266 based on the definition of CSMAR. Table 2 gives the descriptive statistics of the 61 variables.

267 -----  
268 Insert Table 1 about here.  
269 -----  
270 -----  
271 Insert Table 2 about here.  
272 -----

273 ***Model Development***

274 All the 893 observations were randomly and proportionally split into two parts. 80% were used

275 as the training data (698 observations, 124 with corporate misconduct) while the other 20%  
276 were the testing data (175 observations, 31 with corporate misconduct). The training data was  
277 used to establish the learning model, and then the performance of the established model was  
278 evaluated adopting the testing data. All the variables were input without feature selection  
279 because of RF's ability to handle higher-order interactions among features.

280 Like other machine learning models, RF has several hyperparameters which need to be  
281 tuned (Breiman 2001; Ma and Cheng 2016). Previous studies (Poh et al. 2018) have mainly  
282 focused on the number of trees  $n_{tree}$  while other hyperparameters need to be meticulously  
283 tuned. In addition to the number of trees  $n_{tree}$ , the maximum depth which each tree will be  
284 split  $d$ , minimum number of samples on a node for branching  $S_n$ , minimum number of  
285 samples in a final leaf  $S_l$ , and features being considered for branching at each step  $mtry$  are  
286 of equal importance. The sampling method could possibly affect the performance of RF. There  
287 is no effective method for simultaneous hyperparameter tuning of this model to the best of  
288 authors' knowledge. Therefore, grid search, a greedy search algorithm, was adopted for this  
289 study. In grid search, all possible initial values of hyperparameters are tested. Table 3 presents  
290 the list of hyperparameters and the search space of each one.

291 -----  
292 Insert Table 3 about here.  
293 -----

294 Each sample of the search space represented a possible set of hyperparameters. With  
295 each set, the dataset was randomly shuffled and the results of prediction were assessed with a  
296 5-fold cross validation method. That is, 5 RF models were created and tested by splitting the  
297 dataset into 5 sections, and then, in 5 steps, keeping one part as the test set and the remaining

298 as the training set. Their average was treated as the overall performance of that combination.  
299 Finally, the best candidate with the highest prediction accuracy was chosen as the  
300 hyperparameter set. These values are presented in Table 3. The processing time of this grid  
301 search by using scikit-learn, a library for machine learning algorithms with python (Pedregosa  
302 et al. 2011), took nearly 7.3 hours on a Core i7-8700T and 8.00 GB of RAM.

303 To assess the performance of RF further, a comparative analysis was conducted with  
304 SVM. SVM is commonly used in statement fraud detection, particularly in the construction  
305 industry. The same training and testing data with RF were scaled and inputted into SVM. In  
306 implementing SVM, two parameters were optimized, namely the penalty constant  $C$  and the  
307 radial basis function (RBF) kernel parameter  $g$ . They were also determined by grid search.  
308 That is,  $C$  and  $g$  were assigned a value from  $\{2^{-10}, 2^{-9}, \dots, 2^9, 2^{10}\}$  with  $2^1$  as the exponential  
309 step. These combinations were tested by 5-fold cross-validation. In this study, the optimal  $C$   
310 and  $g$  values were 64 and 0.0625, respectively.

## 311 **Results and Discussion**

### 312 *1. Variable importance analysis*

313 Variable importance as ranked by RF has the potential to facilitate the analysis of the role of  
314 input variables in corporate misconduct prediction. Fig. 2. depicts the following variables which  
315 are the most influential: ratio of net profits to total profits (X55), board of directors' total pay  
316 (X12), growth rate of total assets (X37), TMT total pay (X13), accounts payable turnover (X42),  
317 total pay for two boards and TMT (X11), current assets ratio (X24), net cash flow from  
318 operating activities per share (X49), ratio of total profits to EBIT (X56), and firm size (X2).

319 Among the top 10 features, 6 are associated with several categories of financial performance  
320 while the others are related to corporate governance. It is apparent that not only financial  
321 performance but corporate governance makes a significant difference in corporate misconduct  
322 prediction.

323 -----  
324 Insert Figure 2 about here.  
325 -----

326 The most important variable is ratio of net profits to total profits (X55), indicating the  
327 earnings capability of a firm. This capability is also represented by ratio of total profits to EBIT  
328 (X56), which is also among the top 10 variables. This shows that violating firms may try to  
329 inflate their profit or earning figures to create an impressive financial prospectus.

330 The second, fourth, and sixth important variables are board of directors' total pay (X12),  
331 TMT total pay (X13), and total pay for two boards and TMT (X11). All of them are associated  
332 with compensation. Regarding the designing and implementing total compensation package,  
333 compensation is a tool used by management for a variety of purposes to further the existence  
334 of the company. Directors with higher compensation are expected to contribute more to  
335 improving board effectiveness (Zhu et al. 2016). Effective board monitoring has been  
336 considered one of the most important mechanisms for preventing opportunistic managerial  
337 behaviors (Fama and Jensen 1983; Lee et al. 2018), such as corporate misconduct. Similarly,  
338 supervisors' compensation has been reported to be relevant to improving accounting  
339 information quality (Ran et al. 2015), which could be explained by supervisors with high  
340 compensation having a greater incentive to monitor directors and members of the TMT. TMT  
341 compensation, however, appears to operate differently than that of directors' and supervisors'.

342 High compensation may provide incentives to engage in fraudulent behaviors for executives to  
343 maximize their personal profits (Harris and Bromiley 2007). The tenth important variable is  
344 firm size. A larger firm is expected to have better internal governance and thus less likely to be  
345 involved in misconduct (Shan 2013). The ranking of these variables demonstrates the  
346 importance of corporate governance in preventing corporate misconduct.

347         The third important variable is growth rate of total assets (X37), reflecting a firm's  
348 growth capacity. Companies that are unable to achieve a certain performance level may be  
349 motivated to commit illegal activities to maintain their continuing growth (Harris 2008). The  
350 other important variables include a firm's operating capacity, ratio structure, and index per share,  
351 respectively. This indicates that any aspects of financial performance with an undesirable level  
352 may provide an incentive for corporate misconduct. Fortunately, those identified important  
353 variables serve to summarize comprehensive financial performance and thus improve the  
354 effectiveness of identifying questionable firms. The above results have important implications  
355 in the process of feature selection when establishing a corporate misconduct prediction model  
356 for construction companies.

## 357 ***2. Comparison between RF and SVM***

358 According to the procedure described in model development, RF were trained, tested, and then  
359 compared with SVM to assess prediction performance. Table 4 shows the prediction results of  
360 RF and SVM. Their performance is very similar across all evaluation matrices. The accuracies  
361 of RF and SVM are both above 80%, indicating their overall performance is acceptable in  
362 predicting corporate misconduct. As we mentioned before, identifying both violating

363 companies and lawful ones is meaningful. When predicting violating observations (label = 1),  
364 RF performs somewhat better than SVM in terms of precision (RF, 0.6667; SVM, 0.6250). The  
365 results show that RF identifies more actual violating observations than SVM among the  
366 observations labeled violating by the two algorithms. When predicting lawful companies (label  
367 = 0), the recall of RF (0.9931) is slightly higher than that of SVM (0.9792). This reflects that  
368 among all the actual lawful companies, more are identified by RF than SVM. In terms of overall  
369 performance, RF performs only a bit worse than SVM, with F1-scores and accuracy lower than  
370 those of SVM. This may be related to the high dimensionality of the dataset and correlated  
371 features, leading to the overfitting of SVM (Hajek and Henriques 2017; Pai et al. 2011).  
372 However, such a dataset and features won't affect the performance of RF. RF is robust even  
373 with high-order interactions among features, as mentioned in the literature review.

374 -----  
375 Insert Table 4 about here.  
376 -----

377 Moreover, both RF and SVM have higher precision, recall, and F-1 scores when the  
378 label is 0 than when the label is 1, showing that both perform better in identifying lawful  
379 observations than violating ones. This may be attributed to the fact that the number of violating  
380 observations is much smaller than that of lawful ones. Due to the somewhat limited sample size  
381 of violating companies, correctly predicting a violating company is more complex than  
382 predicting a lawful company using machine learning tools. As a result, it is difficult to precisely  
383 identify those violating companies. Nevertheless, accurately distinguishing lawful companies  
384 from those questionable ones is still meaningful. By giving those lawful companies an analog  
385 clearance certificate, the regulators could reduce the scale of investigation. Thus, the

386 effectiveness of recognizing corporate misconduct may be subsequently improved.  
387 Simultaneously, investors could have greater confidence in their decision-making when  
388 selecting companies for investment.

### 389 **Conclusion**

390 Corporate misconduct can result in severe consequences, especially in the construction industry.  
391 Though previous studies have identified a great number of factors associated with corporate  
392 misconduct, ranking their importance and using them to predict corporate misconduct in the  
393 construction industry has been previously overlooked. To identify the most influential factors,  
394 this study developed an RF-based model employing a dataset about 873 observations from 97  
395 China construction companies in 2000-2017. Among the 61 used variables, this study identified  
396 10 variables, which represent several aspects of corporate governance and financial  
397 performance, with the greatest association with corporate misconduct. Then, based on the same  
398 dataset and inputs, the performance of RF was compared with that of SVM. The results show  
399 both are effective in predicting corporate misconduct of construction firms.

400         This study is expected to contribute to the field of corporate misconduct prediction.  
401 Using variable importance ranking of RF to explore the most influential factors, this study  
402 presents a method for locating key factors of corporate misconduct and for facilitating greater  
403 understanding of corporate misbehavior. In particular, the role of corporate governance  
404 deserves more attention in alleviating corporate misconduct. By employing RF and comparing  
405 it with SVM, this research demonstrates the feasibility of RF in predicting corporate misconduct  
406 in the Chinese construction industry. RF may provide a new option for researchers to more

407 effectively identify questionable construction companies. This study also has practical  
408 implications. By exploring the most important factors, regulators and investors can be better  
409 equipped to more efficiently assess a firm's governance and financial condition and foresee the  
410 firm's possible behaviors. RF could be an effective tool for regulators and investors to identify  
411 both law-abiding and violating firms.

412         Though this research has included dozens of variables about corporate governance and  
413 financial performance, adding more features about projects, the firm itself, and its external  
414 environment may enhance the accuracy of corporate misconduct prediction in the construction  
415 industry. The variables used in this study were mainly extracted from a firm's annual reports,  
416 which also contain a textual description of a firm. Thus, combining for sentiment analysis with  
417 text mining tools could be helpful for identifying violating construction firms. The  
418 unsatisfactory performance of RF and SVM in predicting violating observations may be  
419 attributed to the imbalance in the data. The number of violating observations is far less than  
420 that of lawful observations. Supplementation with techniques addressing imbalance data issues  
421 would be beneficial. The RF model developed in this study uses data on Chinese construction  
422 firms only. Additional, similar research covering other industries and contexts is encouraged.

**Fig. 1.** Confusion matrix

**Fig. 2.** Importance ranking of variables

**Table 1** Summary of input variables.

Variable	Description
X0: Capital structure change	Whether there is any change in the company's equity structure during the reporting period. 1 = unchanged, 2 = changed
X1: Relationship of top 10 shareholders	Three dummy variables representing whether top 10 shareholders are unrelated, related, or unconfirmed
X2: Firm size	Number of employees
X3: CEO duality	Whether the board chairman holds the managerial position CEO or president: 1 = yes, 2 = no
X4: Board of directors' size	Number of directors
X5: Board independence	Number of independent directors
X6: Board of supervisors' size	Number of supervisors
X7: TMT size	Number of executives
X8: Board of directors' ownership	Number of shares held by board of directors
X9: Board of supervisors' ownership	Number of shares held by board of supervisors
X10: TMT ownership	Number of shares held by executives
X11: Total pay for two boards and TMT	Total annual emolument of directors, supervisors, and executives
X12: Board of directors' total pay	Total emolument of top 3 directors
X13: TMT total pay	Total annual emolument of top 3 executives
X14: Directors, supervisors, and executives with no salary	Number of directors, supervisors, and executives not receiving emolument
X15: Directors with no salary	Number of directors not receiving emolument
X16: Supervisors with no salary	Number of supervisors not receiving emolument
X17: Board committees	Total number of committees established Number of audit commission, strategic commission, nomination commission, and remuneration and evaluation commission established
X18: The four board committees	
X19: Other board committees	Number of other commissions established Three dummy variables representing whether independent directors work in the same, different or unconfirmed place with the firm. When the number of independent directors is zero, the value is null
X20: Working places consistency	
X21: Directors' meetings	Number of board of directors meetings

X22: Supervisors' meetings	Number of board of supervisors meetings
X23: Shareholders' meetings	Number of shareholder meetings
X24: Current assets ratio	Total current assets / total assets
X25: Ratio of working capital	(Current assets - current liabilities) / current assets
X26: Fixed assets ratio	Net fixed assets / total assets
X27: Ratio of shareholders' equity to fixed assets	Shareholders' equity/net fixed assets
X28: Current liabilities ratio	Total current liabilities / total liabilities
X29: Current ratio	Current assets / current liabilities
X30: Quick ratio	(Current assets – inventories) / current liabilities (Net profits + income tax + financial expenses) / financial expenses
X31: Times interest earned	
X32: Net cash flow from operating activities / current liabilities	Net cash flow from operating activities / total current liabilities
X33: Ratio of debt to assets	Total liabilities / total assets
X34: Ratio of long-term borrowings to total assets	Fixed assets / operating income  (Total liabilities) / (total assets - net intangible assets - net goodwill)
X35: Ratio of liabilities to tangible assets	
X36: Ratio of equity to debt	Total owners' equity / total liabilities (Ending total assets - beginning total assets) / beginning total assets
X37: Growth rate of total assets	
X38: Ratio of accounts receivable to income	Accounts receivable / operating income
X39: Accounts receivable turnover	Operating income / ending accounts receivable
X40: Ratio of inventories to income	Inventories / operating income
X41: Inventories turnover	Operating costs / ending inventories
X42: Accounts payable turnover	Operating costs / ending accounts payable
X43: Current asset turnover	Operating income / ending balance of current assets
X44: Ratio of fixed assets to income	Fixed assets / operating income
X45: Fixed asset turnover	Operating income / ending balance of net fixed assets
X46: Total assets turnover	Operating income / ending balance of total assets
X47: Earnings per share	Net profits / ending paid-in capital Ending owners' equity at period-end / ending paid-in capital
X48: Net assets per share	
X49: Net cash flow from operating activities per share	Net cash flow from operating activities / ending paid-in capital
X50: Return on assets	Net profits / balance of total assets
X51: Net profits margin of current assets	Net profits / balance of current assets
X52: Net profits margin of fixed assets	Net profits / balance of fixed assets
X53: Return on equity	Net profits / balance of shareholders' equity
X54: Earnings before interest and tax (EBIT)	Net profits + income tax expense + financial expenses
X55: Ratio of net profits to total profits	Net profits / total profits

X56: Ratio of total profits to EBIT	Total profits / EBIT
X57: Ratio of EBIT to total assets	EBIT / total assets
	(Operating income - operating costs) / operating income
X58: Gross operating margin	
X59: Selling expense ratio	Selling expenses / operating income
X60: Operating margin before interest and taxes	(Net profits + income tax expense + financial expenses) / operating income

606 **Table 2.** Descriptive statistics (Mean ± St. Dev.) on financial variables

Variable	Mean ± St. Dev.	Variable	Mean ± St. Dev.
X0	1.6±0.49	X31	5.15±90.72
