| 22 | ABSTRACT |
| 23 | Pedestrian are vulnerable to severe injury and mortality in the road crashes. Understanding the essence |
| 24 | of the pedestrian crash is important to the development of effective safety countermeasures and |
| 25 | improvement of social well-being. It is necessary to measure the exposure for the quantification of |
| 26 | pedestrian crash risk. The primary goals of this study are to explore the efficient exposure measure for |
| 27 | pedestrian crash, and identify the possible factors contributing to the incidence of pedestrian crash. In |
| 28 | this study, amount of travel was estimated based on the Travel Characteristic Survey (TCS) data in 2011, |
| 29 | and the crash data were obtained from the Transport Information System (TIS) of the Hong Kong |
| 30 | Transport Department during the period from 2011 to 2015. Total population, walking frequency and |
| 31 | walking time were adopted to represent the pedestrian exposure to road crash. The effect of trip purpose |

- 32 on pedestrian crash was evaluated by disaggregating the pedestrian exposure proxies by purpose. Three
- random-parameter negative binomial regression models were developed to compare the performances of 33

the three pedestrian exposure proxies. It was found that the model in which walking frequency was used as the exposure proxy provided the best goodness-of-fit. Frequency of walking back home, among other trip purposes, was the most sensitive to the increase in pedestrian crash risk. Additionally, increase in the frequency of pedestrian crash was correlated to the increases in the proportions of children and elderly people. Furthermore, household size, median household income, road density, number of non-signalized intersection as well as number of zebra crossings also significantly affected the pedestrian crash frequency. Findings of this study should be indicative to the development and implementation of effective traffic control and management measures that can improve the pedestrian safety in the long run.

- **Keywords**: Pedestrian safety, exposure, travel purpose, crash prediction model

1 **1. INTRODUCTION**

3

2 There are more than 1.2 million road deaths every year. Pedestrians are vulnerable to death and severe 3 injury on roads (Zegeer and Bushell, 2012; Wang and Kockelman, 2013; World Health Organization, 4 2015; Cai et al., 2016). 11% and 16% of road deaths were pedestrians in the United States and Canada, 5 respectively (Miranda-Moreno et al., 2011). Particularly, in Hong Kong, 64% of road deaths were pedestrians in 2016. The likelihood of mortality of pedestrian on road was 17 times higher than that of 6 7 vehicle passengers and 6 times higher than that of drivers (Lam et al., 2013; Hong Kong Transport 8 Department, 2016). On the other hand, over 89% of daily commuter trips in Hong Kong are made by 9 public transport where walking is the primary access to and from the public transit stations (Hong Kong 10 Transport Department, 2012; Li and Loo, 2016). What's more, walkability has attracted the attention from urban and transport planners where pedestrian safety is one of the key attributes. To this end, it is 11 12 crucial to identify the factors contributing to the higher risk of pedestrian injury and mortality on roads 13 (Abdel-Aty et al., 2013; Lee et al., 2015a; Amoh-Gyimah et al., 2016; Cai et al., 2016; Cai et al., 2017).

14

15 A number of studies have attempted to model the pedestrian crash frequency (Miranda-Moreno et 16 al., 2011; Siddiqui et al., 2012; Lam et al., 2014; Lee et al., 2015b; Amoh-Gyimah et al., 2016; Ma et al., 17 2017). Efficient exposure measurement is necessary for better understanding of safety assessment among different (space and time) entities. Vehicular traffic volume and its derivatives like vehicle-kilometer and 18 19 vehicle-hour are commonly adopted as the exposure for vehicular crash modelling, given the advances 20 in automatic vehicle detection techniques (Qin et al., 2006; Pei et al., 2012). However, it remains difficult 21 to obtain accurate pedestrian counts, especially for long-term and extensive monitoring and evaluation. 22 Despite that the collection of high-quality pedestrian count data may be possible at specified locations, 23 it is rare that robust measure of the exposure, in terms of the walking frequency and time, for macroscopic 24 pedestrian crash modeling has been established.

25

Additionally, travel purpose could also affect the pedestrian behavior and therefore the pedestrian crash incidence (*Bao et al., 2017*). Travel is indeed a derived demand, either direct or indirect, of

economic activities including work, education, trade and recreation. For example, a work-related activity 1 involves travel between the place of residence and the workplace. There is a supply of labour in one 2 3 location (residence) and a demand for labour in another (workplace). Therefore, travel (commuting) is 4 directly derived from the relationship between the two locations. To this end, not only the time, location 5 and mode of movements of people are of interest, but also the need of access to economic activities (e.g. work, education and recreation, etc.) should be of concern. Activity-based transport demand modeling 6 7 has been receiving more and more attention in the past decades (Bowman, 1998; Bhat and Koppelman, 8 1999; Bhat and Singh, 2000; Bowman and Ben-Akiva, 2001; Recker, 2001; Miller and Roorda, 2003; 9 Ettema et al., 2004; Bhat et al., 2013). In conventional pedestrian crash prediction model, population has 10 been widely used as the proxy to the crash exposure (Wier et al., 2009; Cottrill and Thakuriah, 2010). However, travel demand could vary among different population groups, and more specifically by time, 11 12 location and activity purpose. It is therefore of essence to estimate the pedestrian crash exposure based 13 on the derived transport demand by different travel purposes (e.g. economic activities) (Chliaoutakis et al., 1999, 2005; Abdel-Aty et al., 2013; Elias and Shiftan, 2014; Lee et al., 2014, 2015a). Furthermore, 14 15 possible trip generation factors that could affect the accessibility to different economic activities, and 16 then the pattern of travel activities by purposes and therefore the crash risk, should be examined (Naderan and Shahi, 2010; Siddiqui et al., 2012; Bao et al., 2017; Zou et al., 2017). 17

18

This study attempts to explore efficient exposure measure for pedestrian crash and to identify the factors contributing to the incidence of pedestrian crash at the zonal level. Additionally, the moderating effects on the association between pedestrian crash, exposure and possible risk factors by travel purpose would be attempted.

23

The remainder of the paper is organized as follows. Section 2 provides a review of literature on pedestrian safety. Section 3 describes the data. Methodology and model formulation are presented in Section 4. Section 5 shows the results of the crash prediction models. After that, discussion is presented in Section 6. Lastly, Section 7 summarizes the study and provides the recommendations for future study
 respectively.

3 4

5 2. LITERATURE REVIEW

Prevalence of pedestrian crash is one of the main streams for the pedestrian safety analysis. For the 6 7 prevalence of pedestrian crash at the zonal level, increase in the population density was often found 8 correlated to the increase in pedestrian crash frequency (Wang and Kockelman, 2013; Wang et al., 2017). 9 Land use and transport network characteristics also affected the pedestrian safety. For instances, increase 10 in the proportion of commercial area, road density, number of signalized intersections can increase the 11 probability of pedestrian crash, considering the increase in the activity amount and conflicts between 12 pedestrian and vehicular traffic (Loukaitou-Sideris et al., 2007; Wier et al., 2009). Household 13 demographic and socio-economic characteristics including car ownership, age and household income 14 were correlated to the prevalence of pedestrian crash (Noland and Quddus, 2004; Ponnaluri and Nagar, 15 2010; Lee et al., 2015b). Increase in the number of jobs was found to increase the likelihood of pedestrian 16 crash occurrence (Kim et al., 2006; Lee et al., 2015b). The abovementioned factors can indeed affect the 17 need of travel (derived demand of economic activity), and thus the travel behavior and crash risk. It is 18 necessary to consider the moderating effect of the amount of travel by purpose, when measuring the 19 association between pedestrian safety and possible factors.

20

Population and population density are often adopted to represent the pedestrian exposure because they can be extracted easily and directly from the census dataset *(Wier et al., 2009; Cottrill and Thakuriah, 2010; Siddiqui et al., 2012; Lee et al., 2015b; Wang et al., 2017).* However, using population as the proxy does not consider the habit, and thus the differences in the amount of travel and behavior among different population groups. The results of association measure using population as the exposure could be biased.

Another alternative for measuring the exposure to pedestrian crash is the number of personal trips 1 2 estimated using the conventional four-step model (Bao et al., 2017). However, the transport mode of 3 every trip leg within a single trip had to be distinguished (Allsop, 2005). For instances, a multi-modal 4 trip (home – metro – bus – office) could generate three walking trip legs, taking into account the access 5 to public transport station and transfer between modes. Therefore, the exposure could be underestimated when only the number of Origin-Destination trips is used as a proxy (Lam et al., 2014). On the other 6 7 hand, observational pedestrian counting approach may not be able to incorporate the effect of pedestrian 8 characteristics including demographics and travel purpose when evaluating the relationship between 9 pedestrian behavior and safety (Lam et al., 2014).

10

Travel characteristics survey through household interview can be exploited as a way for estimating 11 12 the pedestrian exposure. It is possible to deduce the origin, destination and time of each walking trip (and 13 trip leg) from the household travel survey data. More importantly, attributes of every trip could be linked to the personal and household characteristics of the commuter. This could help improve the understanding 14 15 on the association between pedestrian crash occurrence and personal factors (Allsop, 2005; Lam et al., 16 2013; Papadimitriou, 2016). The effect of travel purpose on the risk of vehicular crashes had received much attentions (Elias et al., 2010; Naderan and Shahi, 2010; Lam et al., 2013). Indeed, trip purposes 17 18 may also affect the pedestrian behavior, in terms of walking path choice, walking speed, crossing location 19 and time, and propensity of convicted crossing behavior (Sze and Wong, 2007; Lavieri, 2018). For 20 instances, distraction by mobile phone use and social interactions were correlated to the prevalence of pedestrian crash at the crosswalk (Elias and Shiftan, 2014). Therefore, the intervention effect of trip 21 22 purposes for the association between pedestrian crash, exposure and possible factors should not be 23 ignored. Temporal variations in the environment, traffic and road user behavior could also affect the association between pedestrian safety and possible risk factors (Mason, 1979). Attempts had been made 24 25 to examine the temporal effect on safety, with time scales varying from annually (*Castro et al., 2012*), daily (Mason, 1979; Ma et al., 2017) to hourly (Lam et al., 2013). Spatial and temporal variations in the 26 27 exposure are crucial to the association measure between pedestrian crash and possible factors (Pahukula 1 et al., 2015). Some examples of pedestrian exposure measures used in previous studies are summarized

2 in **Table 1**.

3

TABLE 1. Some examples of pedestrian crash exposure measures

| Exposures | References | | Advantages | | Limitations |
|---|---|--------|--|---|--|
| Population / population density | Wier et al., 2009 Cottrill and Thakuriah, 2010 Siddiqui et al., 2012 Lee et al., 2015b Wang et al., 2016 | A | Easy to extract | A | Not considering the difference in the amount of travel between individual |
| Pedestrian volume from observational survey | Lam et al., 2014 | A | Considering the spatial and temporal distributions of pedestrian exposure | A | Not considering the effects of demographics and other personal characteristics |
| Trip generation estimates from four-step model | Bao et al., 2017 | > | Considering the effects of land use, demographics and socio- economic characteristics on travel demand | A | Not considering the multi-modal (walking and non-walking) trip legs |
| Walking frequency from household travel survey | Elias et al., 2010 Naderan and Shahi, 2010 Lam et al., 2013 | A A | Considering the effects of demographics and travel purpose on safety Considering the temporal effect on safety | A | Should consider multi-modal (vehicle and pedestrian) exposures |

4

5 This study attempted to address the above issues by measuring the time-varying pedestrian 6 exposure, in the terms of walking frequency and walking time, aggregated at zonal level for the pedestrian 7 crash prediction model. The proposed method also considered the effect of trip purpose, personal and 8 household characteristics on pedestrian safety, based on the data captured from the household travel 9 survey.

1

2 **3. DATA**

3 The dataset is established by integrating the information captured from different sources: (i) The police 4 crash record from the Traffic Information System (TIS) maintained by the Hong Kong Transport 5 Department; (ii) the household travel data from the 2011 Travel Characteristic Survey (TCS) and Annual Traffic Census (ATC) data from the Hong Kong Transport Department; (iii) the data of population census 6 7 from the Hong Kong Statistics and Census Department; and (iv) the zoning scheme and land use planning 8 data from the Hong Kong Planning Department. The above-mentioned data were matched to the specified 9 spatial unit, Tertiary Planning Unit (TPU), using the Geographical Information System (GIS) technique 10 (Lee et al., 2014; 2015b; Cai et al., 2016; Cai et al., 2017). The entire territory of Hong Kong is divided into 289 TPUs. Considering the problem of prevalence of zero crash count when the data is highly 11 12 disaggregated (of small zone size and/or short time period), the 289 TPUs were aggregated into 26 zones.

13

In this study, 12,672 pedestrian crashes occurred on the weekdays during the period from 2011 to 2015 were captured from the TIS. TIS database consists of three profiles, namely crash environment, vehicle attributes, and casualty characteristics. Since the precise information on location and time of every single crash is available, it is possible to allocate the crashes into units by space (26 zones) and time (24 hours) when evaluating the spatial-temporal variations in pedestrian crash incidence. Finally, there are 624 units for the proposed pedestrian crash prediction models. The distribution of pedestrian crash (by zone) is depicted in **Figure 1**.

21

As shown in Figure 1, the pedestrian crashes are concentrated in Central Kowloon and North shore of Hong Kong Island (colored in red). It is not surprising since they are the Central Business Districts (CBDs), and the interactions between pedestrian and vehicular traffic are prevalent. This justifies the need to estimate the pedestrian exposure, in terms of the amount of travel by walking.

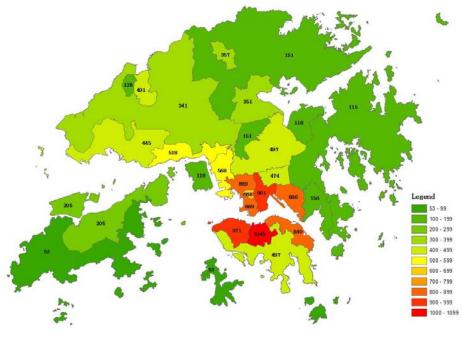

FIGURE 1 Spatial distribution of pedestrian crash

For the pedestrian exposure, the walking frequency and walking time were estimated based on 4 5 the Travel Characteristics Survey (TCS) which was conducted by the Hong Kong Transport Department. 6 The survey was conducted during the period from September 2011 to March 2012. Of the 2.36 million 7 households in Hong Kong, 35,401 households (1.5%) were surveyed in TCS. The survey captured the 8 details of 136,122 trips (including 122,237 motorized trips and 13,885 walk-only trips) made by 101,385 9 people during the weekdays. Such 136,122 reported trips of selected households could be projected to 10 that of all households in Hong Kong using a set of expansion factors, in accordance to the demographics 11 and socio-economic characteristics of the households. For instances, the 122,237 motorized trips reported 12 could be transformed into 12.6 million person-trips per day for the whole Hong Kong. To eliminate the biases of trip estimates attributed to the under-reporting of surveyed households, the trip estimates were 13 14 validated using the independent datasets including the screenline traffic counts and public transport 15 ridership statistics (Hong Kong Transport Department, 2012).

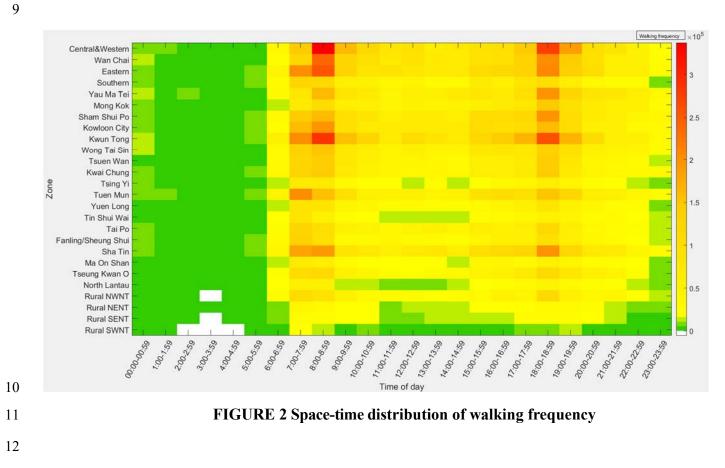

16

1 2

3

A motorized trip was defined as the trip that involved at least one motorized mode (i.e. bus, metro, taxi and car, etc.). One motorized trip can have more than one walking trip leg (e.g. variable of interest

in current study). For each trip, the information on origin location, destination location, departure time, 1 2 arrival time and transport mode of each trip leg was captured. In this study, walking frequency refers to 3 the total number of walking trip legs, and walking time refers to the total time spent on walking 4 respectively. The total walking frequency and walking time for the whole Hong Kong were estimated 5 using the expansion factors concerned. For instances, the total walking frequency derived was 28.7 million per day. The distribution of walking frequency by the 624 analysis units (i.e. 26 zones x 24 hours) 6 is depicted in Figure 2. As shown in Figure 2, four analysis units had zero walking trip (leg). They were 7 8 all in the rural area and before dawn (e.g. from 2.00 am to 4.59 am).

Variations in the pedestrian crash frequency and walking frequency, over time of the day, are depicted in **Figure 3**. The peak walking frequencies occurred during the periods from 8:00 am to 8:59 am and from 6:00 pm to 6:59 pm, respectively. Except during the period from mid-night to dawn (e.g. from 11.00 pm to 5:59 am), walking frequency was the lowest in the middle of the day while the pedestrian crash frequency was consistently high throughout the period from 8:00 am to 7:00 pm. Because of the discrepancy between crash and walking frequency, bias may exist in the association measure when only the aggregated walking frequency was used as the exposure for the pedestrian crash prediction model. In this study, the walking frequency and walking time of different trip purposes in different time periods were considered. Specifically, trip purpose could be categorized into six: home, work, school, shopping, dining and others (*Miller and Roorda, 2003; Bhat et al., 2013; Allahviranloo and Recker, 2015*).

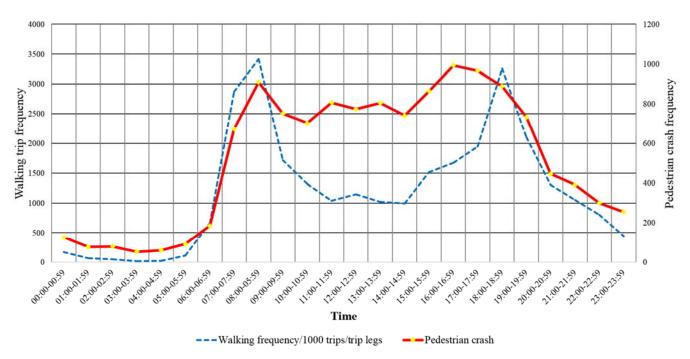

FIGURE 3 Temporal distributions of pedestrian crash frequency and walking frequency

10

8 9

11 Taking into account the effect of multi-modal (vehicle and pedestrian) exposure, the vehicular traffic was also considered in the proposed crash prediction model. For instances, the information on annual 12 average daily traffic (AADT) (and hourly count) was obtained from the Annual Traffic Census (ATC) 13 dataset in 2011 maintained by the Hong Kong Transport Department. ATC covers 87% of all public roads 14 15 in Hong Kong. Additionally, information on age, employment status, household size and household income were obtained from the population census. Furthermore, the transport network and traffic control 16 17 attributes including number of signalized and non-signalized intersections, and number of zebra crossings, 18 were also incorporated into the proposed model. The above data was matched with the crash, traffic count

and pedestrian exposure data using the GIS technique. Table 2 summarizes the characteristics of the

- 2 candidate variables.
- 3

| Number of signalized intersections | 56.81 | 39.60 | 0 | 141 |
| Number of non-signalized intersections | 798.19 | 342.02 | 156 | 1,544 |
| Number of zebra crossings | 10.23 | 8.89 | 0 | 31 |

TABLE 2. Summary statistics of the variables used in current study

As shown in Table 2, walking frequency and time of back home trip were predominant among the

six travel purposes. Back home trip constituted to 45% of walking frequency and 46% of walking time respectively. For the mandatory travel (e.g. commuting), work trip constituted to 25% of walking frequency and 24% of walking time respectively. For the demographic characteristics, vulnerable group (i.e. elderly and children) constituted to one-fourth of the overall population. In Hong Kong, the average household size was 2.8 person, and the proportion of household with more than three members was 34%.

6 Prior to the association measure between pedestrian crash, exposure and possible factors, the 7 variance inflation factor (VIF) was estimated to identify any possible collinearity among the variables. 8 The candidate variables with VIF greater than five (e.g. proportion of unemployment, number of 9 signalized intersections) were not considered in the consolidated model. As the main purpose of current 10 study is to identify the significant contributory factors (and their effects) to pedestrian crash, it is 11 necessary to exclude the (theoretically less important) correlated variables, even which the estimates of 12 remaining correlated variables might be biased (Tay, 2017).

- 13
- 14

15 **4. METHOD**

Poisson and negative binomial regression models are the most commonly used approaches for crash occurrence *(Wong et al., 2007)*. Results of over-dispersion test indicated that the data was subject to significant over-dispersion at the 1% level. Therefore, negative binomial regression model was preferred to the Poisson model.

20

Negative binomial regression can be derived from the Poisson model by introducing an unobserved
 heterogeneity error term *τ*, following the gamma distribution with mean of 1.

23
$$y_{it} \Box f(y_{it} | \mu_{it}, \tau_{it}) = \frac{\exp(-\mu_{it} \cdot \tau_{it})(\mu_{it} \cdot \tau_{it})^{y_{it}}}{y_{it}!}$$
(1)

1 Let $E(y_{it}) = \mu_{it}$ be the expected number of pedestrian crashes in zone *i* (*i*=1,2,3...,26) for time period 2 *t* (*t*=1,2,3...,24). The density function of negative binomial distribution $p(\cdot)$ can be further derived 3 as:

4
$$p(y_{it}) = \frac{\Gamma(y_{it} + \alpha^{-1})}{y_{it}\Gamma(\alpha^{-1})} (\frac{\alpha^{-1}}{\alpha^{-1} + \mu_{it}})^{\alpha^{-1}} (\frac{\mu_{it}}{\alpha^{-1} + \mu_{it}})^{y_{it}}$$
(2)

5 where the mean of y_{it} was given by $E(y_{it}) = \mu_{it}$ and $\operatorname{var}(y_{it}) = \mu_{it}(1 + \mu_{it})$. $\Gamma(\cdot)$ stands for Gamma 6 function and α presents the over-dispersion parameter. Furthermore, μ_{it} was given as follow:

7
$$\ln(\boldsymbol{\mu}_{tt}) = \boldsymbol{\beta}_0 + \boldsymbol{x}_{tt}^T \cdot \boldsymbol{\beta}$$
(3)

8 where \mathbf{x}_{it} was the column vector of exogenous variables corresponding to entity i and time period t. 9 $\boldsymbol{\beta}$ was a vector of parameters of \mathbf{x}_{it} while $\boldsymbol{\beta}_0$ is the constant term.

10

For the conventional count data (Poisson and negative binomial) models, the parameters were 11 12 assumed to be fixed. However, as the crash data were aggregated over specified zone and time period, the effect of a possible factor on crash incidence may vary. For example, risk perception could affect the 13 pedestrian behavior, and therefore contribute to crash incidence. The association between risk perception 14 15 and crash frequency was not revealed in the aggregated data. In this case, risk perception varied across different individuals, but was not explicitly observed. It was known as unobserved heterogeneity. 16 17 Therefore, assuming the parameters to be constant across observations could result in biased parameter 18 estimations when they were indeed varying across observations (Savolainen et al., 2011; Xiong and 19 Mannering, 2013; Mannering et al., 2016).

20

To capture the variation in the effect of possible factor on the crash incidence across individuals, the random parameter approach has been applied (*Anastasopoulos and Mannering, 2009*). Specifically, parameter corresponding to the specific factor is no longer treated as constants but vary cross individuals (*Train, 2009*). Assumed that β was associated with the density function of $f(\beta)$, Eq. (3) becomes:

$$P(y_{it}) = \int p(y_{it} \mid \boldsymbol{\beta}) f(\boldsymbol{\beta}) d\boldsymbol{\beta}$$
(4)

If random parameter vector β collapsed to the case that only constant was found randomly distributed, random parameter model was consistent to random-effect model. Halton draws have been used to solve the random-parameter models and provided stable results (*Train, 2001*). Three indicators are used for evaluating the goodness-of-fit of the random-parameter models, namely Pseudo ρ^2 , Akaike information criterion (AIC) and Bayesian information criterion (BIC).

7

8

9 5. ESTIMATION RESULTS

10 Three random-parameter negative binomial regression models were established to measure the 11 association between pedestrian crash frequency and possible risk factors. The exposure to pedestrian 12 crash was proxied by the zonal population in Model 0, walking frequency in Model 1 and walking time 13 in Model 2 respectively. Results of the three estimated models were given in **Table 3**.

14

| Variables | Model 0 | | Model 1 | | Model 2 | |

| AIC | 4837.80 | | 3714.35 | | 3751.12 | |
| BIC | 487 | 5.73 | 379 | 8.64 | 382 | 4.54 |

1

As shown in Table 3, Pseudo ρ^2 of Model 0, Model 1 and Model 2 were 0.04, 0.27 and 0.26, AICs of Model 0, Model 1 and Model 2 were 4,837.80, 3,714.35 and 3,751.12, and BICs of Model 0, Model 1 and Model 2 were 4,875.73, 3,798.64 and 3,824.54, respectively. Model 1 was superior to the two other counterparts, given the highest Pseudo ρ^2 while the lowest AIC and BIC. This indicated that model using the walking frequency as the proxy for pedestrian exposure had the best prediction performance.

7

8 For the model using walking frequency as proxy for pedestrian exposure (Model 1), as shown in 9 Table 3, walking frequency (for back home, work, study and shopping), traffic flow, proportion of 10 population age below 15, age above 64, proportion of household with more than 3 members, median 11 household income, road density, number of non-signalized intersection and zebra crossing all 12 significantly affected the crash frequency, at the 1% level. In particular, increase in walking frequency

(coefficient ranged from 0.03 to 0.25), proportion of vulnerable population (age below 15, coefficient = 1 2 8.02; and above 64, coefficient = 4.15), median household income (0.002), road density (0.02), and number of non-signalized intersection (0.04) and zebra crossing (0.01), were correlated to the increase 3 4 in pedestrian crash frequency. In contrast, increases in traffic flow (-0.03) and household with more than 5 3 members (-2.44) were correlated to the reduction in pedestrian crash frequency. Additionally, effects of proportion of young population, and household with more than 3 members and median household 6 7 income on crash frequency varied across the observations. Similar results could be revealed for the model 8 using walking time as the proxy for pedestrian exposure (Model 2).

TABLE 4. Elasticity of pedestrian crash frequency

11

Table 4 illustrates the elasticity estimates of walking frequency by travel purpose. Increase in pedestrian crash frequency is less proportionate to that of walking frequency, as the elasticities are all less than one (0.25, 0.11, 0.08, 0.07 and 0.03 for back home, work, school, shopping and other trips respectively). Nevertheless, the effect of back home travel is dominant among other travel purposes.

16

17 6. DISCUSSION

In this study, pedestrian crash prediction model using walking frequency as the proxy for pedestrian exposure was found superior to that using zonal population and walking time. Though population is often used as the proxy for exposure as it is readily available in the census dataset, it is not necessary that every individual would make the same number of (walking) trips in a specified period of time. On the other hand, population could only reflect the number of residents in the area concerned, it should not
necessarily reflect the exposure of commuters travelling in the area.

3

4 Besides, model using walking frequency as the proxy better reflected the prevalence of vehicularpedestrian interaction, as compared to that using walking time. For instances, increase in the number of 5 walking trip by ten times was more likely correlated to the increase in the frequency of vehicular-6 7 pedestrian interaction by the same extent, however, it might not be the case for increasing the walking 8 time by ten times (it could be attributed to the increase in the time spent on the footpath or waiting at the crosswalk) (Siddiqui et al., 2012; Cai et al., 2017; Wang et al., 2017). On the other hand, in the household 9 10 travel survey, the reliability of (self-reported) information on walking frequency could be higher than that of walking time, because of the variation of time perception among individuals and thus the 11 12 unreliability of self-reported walking time (Chu, 2003; Greene-Roesel et al., 2007). On the other hand, 13 increase in traffic flow was correlated to the reduction in pedestrian crash. It could be attributed to the increase in safety awareness of the pedestrian due to the increase in traffic volume. Then, the propensity 14 15 of reckless crossing behavior could be reduced, and therefore, the risk of pedestrian crash reduced.

16

17 6.1 Travel Purpose

Increase in the pedestrian exposure was found correlated to the increase in the frequency of pedestrian 18 19 crash. However, as shown in Figure 2, the pedestrian crash rates (per unit walking frequency) were 20 remarkably high during the noon (12.00pm – 1.59pm) and late afternoon (3:00pm - 4:59pm), even though the overall walking frequency was very low during the periods. It could be attributed to the reckless 21 22 behavior of the pedestrian, since it is the prime time for back home travel during the periods (Clarke et al., 2006; Anderson, 2008; Devlin et al., 2010; Liu and Yue, 2011; Palamara and Broughton, 2013). 23 Considering the distribution of walking frequency by travel purpose, back home travel was dominating 24 25 during the noon (about 35%) and late afternoon (about 75%) periods. Indeed, pedestrian inattentiveness was one of the top contributory factors to road crashes in recent years (Hong Kong Transport Department, 26 27 2012-2016). These are consistent to the findings of earlier studies that the travel purpose and time of the

day can affect the travelers' behavior and thus the safety level on roads (Elias et al., 2010; Naderan and 1 Shahi, 2010). This could shed light on the setting of road safety target, and then better planning of road 2 3 safety strategies that can enhance the safety of vulnerable pedestrian group at specified time periods and 4 locations (Wong et al., 2006; Sze et al., 2014; Sze and Christensen, 2017). In particular, it is necessary to 5 improve the road user education and enforcement measures that could enhance the safety awareness of pedestrian on their way back home (Wong et al., 2008). Yet, the association between safety perception 6 7 and safety risk of individual pedestrian was blurred when the crash data was aggregated by time and zone. 8 It would be worth exploring the factors affecting the safety perception of pedestrian and thus crash 9 involvement using observational and/or perceptional survey.

10

11 **6.2 Socio-demographics**

12 Age could also affect the frequency of pedestrian crash. In particular, increases in the proportions of 13 children and elderly people were correlated to the increase in the frequency of pedestrian crash (Fontaine 14 and Gourlet, 1997; Noland and Quddus, 2004; Palamara and Broughton, 2013; Jiménez-Mejías et al., 15 2016). It could be attributed to the variations in the obedience of traffic rule, risk perception and safety 16 awareness across different age groups (Ponnaluri and Nagar, 2010; Siddiqui et al., 2012). In particular, 17 the children and younger teens had a higher propensity to involve in reckless behavior on roads (Tay, 18 2003). For the elderly pedestrian, the high crash risk could be attributed to the degradation of cognitive 19 performance, gap acceptance and impaired mobility (Fontaine and Gourlet, 1997; Noland and Quddus, 2004; Palamara and Broughton, 2013; Jiménez-Mejías et al., 2016). Therefore, targeted road user 20 education programs should be conducted in the schools and community centers. 21

22

Increase in household median income was found correlated to the increase in pedestrian crash incidence. It could be attributed to the difference in safety perception and choice decision across population of different income levels. In particular, the trade-off between travel cost and crash risk could vary with the value of time of commuter *(Tay, 2003)*. Such finding could be indicative to the planning and design of built environment, especially for the enhancement of accessibility, and therefore the safety

performance, in accordance to the need of different population demographics and socio-economics 1 2 (AECOM Asia, 2010; Mannings (Asia) Consultants, 2010; MVA Hong Kong, 2013). Additionally, 3 increase in the proportion of household with more than 3 members was found correlated to the reduction 4 in the frequency of pedestrian crash. It could be because the vulnerable road users (i.e. children and 5 elderly) are usually accompanied by other household members, in particular the domestic helper or health care taker, for the household with more members, which was commonly seen along the streets in Hong 6 7 Kong. It could then enhance the safety awareness and reduce the crash risk on roads (Huang et al., 2010; 8 *Cai et al.*, 2017). This is indicative to the road safety education and promotional strategies targeted to the 9 caretakers of vulnerable pedestrian group (Sze and Christensen, 2018).

10

11 **6.3 Transport system characteristics**

12 Last but not the least, transport system characteristics including road density (road length per unit area), 13 number of non-signalized intersection and number of zebra crossing could affect the pedestrian safety. 14 Specifically, increase in road density was found correlated to the increase in pedestrian crash. It could be attributed to the increase in the potential vehicular-pedestrian interactions, and thus the incidence of 15 16 pedestrian crash. This should also be applicable to the association between pedestrian crash, number of 17 non-signalized intersection, and number of zebra crossing (Varhelyi, 1997). This implied that installation 18 of signal control at the intersection and crosswalk (segregating the conflicting vehicular and pedestrian 19 streams by time and space) might effectively reduce the incidence of pedestrian crash. (Castro et al., 20 2012; Siddiqui et al., 2012). This is indicative to the planning of pedestrian infrastructure and traffic management & control strategies that could mitigate the vehicular-pedestrian interaction, and therefore 21 22 the pedestrian crash potential (Sze and Wong, 2007). It was noticed that the signs of annual average hourly 23 traffic and number of zebra crossing were difference across the three models. When the amount of 24 walking is not considered (using zonal population as the proxy), it is expected that the crash incidence 25 would increase with traffic volume and decrease with the presence of zebra crossing. The pedestrian perception and behavior are indeed correlated to the traffic volume and traffic control. Therefore, when 26 27 the amount of walking is used as the proxy (effect of pedestrian behavior is incorporated implicitly), the

effects of traffic volume and presence of zebra walking could be reversed. Therefore, increase in
 pedestrian crash is correlated to the reduction in annual average hourly traffic and the presence of zebra
 crossing.

6 7. CONCLUSION AND FUTURE RESEARCH

7 This paper contributes to the literature by developing a pedestrian crash prediction model, at zonal level, 8 that takes into account the effects of pedestrian exposure and travel purpose. The contribution of this 9 paper is twofold. Firstly, we sought an alternative approach for measuring the pedestrian exposure based 10 on the comprehensive household travel characteristics survey data. Therefore, the effect of the difference 11 in the amount of walking across population groups on crash incidence can be considered. In particular, 12 the model that applied the walking frequency as the proxy to pedestrian exposure was superior to that 13 using zonal population and walking time. Secondly, the effect of travel purpose on pedestrian crash risk 14 was examined. The exposure was discretized by hours of the day and travel purposes. Results indicated 15 that the crash risk of back home walking trip was more profounding than that of other travel purposes. 16 Additionally, effects of confounding factors including age, household size, household income, road 17 density and intersection control on pedestrian safety were revealed. Results should be indicative to the 18 targeted road user education, enforcement and traffic control measures that could enhance the safety 19 awareness of vulnerable pedestrian group, and therefore improve the pedestrian safety in the long run. 20 This is an essence to the promotion of walkability in an aging society like Hong Kong.

21

Yet, in the current study, the association between pedestrian crash incidence, exposure and possible risk factors was measured using the aggregated data by time and zone. Besides, we only considered the pedestrian crash exposure on weekdays, given the availability of travel data. It would be worth exploring the effects of demographics, socio-economics, built environment, and multi-modal (vehicular and pedestrian) traffic flow on the safety perception, and in turn the propensity of reckless behavior of pedestrian, when the trajectory data of individual vehicle and pedestrian are available through
 extensive observational survey in the extended study.
