The present invention relates to a system and method for continually monitoring the spine of a user via device containing electromechanical transducer, processor, delay, transmitter, and a feedback component. Through the device and method of employing, the user will be able to learn and sustain a proper posture, thereby avoiding future back pain.

ADJUSTING SPINAL POSITION BY USER

FIG. 3
The following description of certain exemplary embodiment(s) is merely exemplary in nature and is in no way intended to limit the invention, its application, or uses. Throughout this description, the term “biofeedback” refers to a signal, such as electrical, audible, visual, or sensory, that is delivered to a user in response to a previous action taken by the user, in an effort to train the user to control a body function.

Now, to FIGS. 1-4. Whereas FIGS. 1-4 are presented and discussed individually, they, in total, represent the present invention. Unless otherwise noted, the FIGs refer back to and rely upon each other.

FIG. 1(a) is a graphic of the human spinal column, divided into its various regions, including cervical 101, thoracic 103, lumbar 105, and pelvic 107. Back pain exhibited by the spine, can include neck pain, low back pain, referred pain, and radicular pain. Back pain has been known to be located at or around the cervical region 101 and the lumbar region 105. To the epidemiology of back pain, it has been reported that restricting the forced flexion of posture was associated with a decreased risk of low back pain. This result suggests that restricted forward flexion may be indicative of a more stable lumbar spine that is less susceptible to injury. While not to be bound by theory, it is believed that a posture exhibiting forward flexion will subject the spine to increased compression.

FIG. 1(b) shows posture in forward flexion stance, exhibited in different circumstances: standing 109, working at a desk 111, and working at a standing desk 113. In all circumstances, there is a posture that may be taken which decreases or prevents the occurrence of back pain (“proper”), and a forward flexion posture that may be taken that likely increases occurrence of back pain (“improper”). Through the present invention, it is believed that by maintaining a posture that avoids excessive forward flexion, back pain around the cervical region or lumbar region of the spine can be prevented.

FIG. 2 is an embodiment of the spine monitoring device 200 of the present invention, such devices 200 useful for monitoring the position and condition of the spine during work periods and exercise periods. In particular, the device 200 is used to monitor the cervical region and lumbar region of the spine. FIG. 2, while possessing the component parts of the device, is not reflective of the size of the device 200 in reality. In reality, the device 200 measures under 3 cm, preferably less than 2.5 cm. In one embodiment, the device 200 is micro-size, measuring less that several millimeters. The device 200 possesses an electromechanical transducer 203, a signal processor 205, a delay 207, a transmitter 209, and feedback means 211. In an alternatively embodiment, the device 200 possesses an antenna for communication. The various components can be mounted on a base 201, for example a breadboard. In operation, a signal is generated by the device 200 when the electromechanical transducer 203 is affected beyond an optimum set level, such as angle, pressure, or force.

The electromechanical transducer 203 of the device 200 is useful for detecting a change by or being exerted upon the spine, and then communicating a signal to the device 200. Example of transducers include sensors suitable for measuring pressure, force, acceleration, or velocity, such as an accelerometer, barometer, speedometer, and the like. One or more sensors may be used in conjunction. The sensor is used to provide an actual measurement of the position or condition of the spine. This actual measurement is then compared to the optimum setting of position or condition programmed into the device 200. If the actual measurement is over or under (read: + or –) to the optimum setting, the device 200 will indicate such through its feedback means 211. In one embodi-
The feedback means 211 is used to provide an indicator to the user when the spine position or condition changes beyond the optimum setting outside the allowable deviation. The feedback means 211 can be an audible device, sensory device, visual device, and the like. Audible devices can include alarms, buzzers, etc. In one embodiment, the audible device can be fitted to the ear. Sensory devices can include electrostimulators capable of providing a mild but effective shock to the body of the user or a localized vibration. Such sensory devices can be applied to any body part, for example a finger. Visual devices can include monitors, such as TV monitors, allowing the users to see the movement of various regions of the spine.

The feedback means 211 can be an audible device, sensory device, visual device, and the like. Audible devices can include alarms, buzzers, etc. In one embodiment, the audible device can be fitted to the ear. Sensory devices can include electrostimulators capable of providing a mild but effective shock to the body of the user or a localized vibration. Such sensory devices can be applied to any body part, for example a finger. Visual devices can include monitors, such as TV monitors, allowing the users to see the movement of various regions of the spine.

FIG. 3 is an embodiment of a method of monitoring the spine 300 of the present invention, comprising the steps of attaching a spine monitoring device 301, setting the optimal spine position and/or conditions on the device 303, detecting a change in the user’s spinal condition or position 305, determining if the change is significant 307, and if so, transmitting a signal through the device 309, and adjusting the position of the user’s spine 311. The method contains a loop function, allowing continual detection of the user’s spine condition while the device is in use.

Attaching the monitoring device 301 to the user can include attaching the devices as a complete unit to a body part of the user, such as, for example, fitting it on an ear. The device can also be attached adjacent to the spine, such as on a bony landmark, e.g. L3, with a strapping means such as a belt. If the device is comprised of components separately connected, they can be attached to the body in different locations. Preferably, the device is attached in a location such that it does not interfere with normal movement of the user. In this way, accurate monitoring of the spine’s condition and/or position can be made.

Setting the optimal spinal conditions on the device 303 is performed to input into the device the most suitable condition and/or position of the user’s spine for the avoidance of present or future back pain. The condition and/or position includes spine angle, pressure placed upon the spine, force upon the spine, acceleration by which the spine changes its angle, or velocity by which the spine changes. The most suitable condition and/or position refers to the measurements that are most likely to avoid or prevent the occurrence of back pain. The most suitable condition is preferably specific for each person, and can be determined by previous testings’ on the user’s spine. The setting on the device is reflective of the most suitable condition and/or position with an allowable deviation. The deviation may be around +/-5%. The device may be set by user interfaces including switches, dials, buttons, or computer devices whereby the device is connected to the computer, such computer including software allowing control or setting of the device.

The device is then prepared to detect change in the condition and/or position of the user’s spine 305. Change includes a change in the pressure, force, acceleration, angle, or velocity exhibited by the user’s spine. The device, continually monitoring, will detect the change when a measurement including the deviation is made. Upon the detection of a change, a signal will be sent through the device.

A determination will then be made as to whether the signal is sufficient to cause a present or future negative effect on the spine 307. The signal will be determined sufficient based on time or signal level, for example, after the signal occurs for a certain period of time, it is determined sufficient. The period of time can be from 30 seconds to 1 minute. A negative effect on the spine includes neck pain, back pain, spinal disk injury, spinal inflammation, and sciatica. The negative effect can be
to enhance a current status or to initiate a spinal injury. If the change is not sufficient, the signal is looped back toward detection for continual monitoring. If the change is sufficient, the signal is then transmitted.

Transmitting the signal 309 can include directing the signal in one or more directions. The directions include a biofeedback means and a communication means. As stated previously, the biofeedback means includes audible devices, sensory devices, and visual devices. Communication means can include wireless technology such as an antenna, and wired technology such as fiber optic. By the signal being directed to the biofeedback means, the user is able to adjust his/her spine condition and/or position to bring it again with the optional settings.

Adjusting the spinal position 311 can include adjusting the posture, adjusting the shoulders, adjusting the head, modifying the movement of the body, swing of the arms, and the like. As the adjustment will be temporary and the user will likely go back to his/her original poor posture position, the signal will be looped, allowing for continual monitoring of the spine. Thus, the user will be continually trained, eventually leading to a preferred spinal condition and/or position that will be least likely to cause a present or future negative effect to the spine.

FIG. 4 is an example of a schematic of the present invention, wherein the signal is determined as sufficient to cause a negative effect on the spine, and then forwarded through the biofeedback means. The schematic exhibits a comparator circuit, a storage 403, an absolute value generator 405, a capacitor 407, and an audible device 409.

As shown in the schematic, as the signal comes from the detecting sensor, it can be inserted into a comparator 401 for comparison against the optimum settings. The comparator circuit 401 can be a subtractor. The optimum setting, as entered into the device via user interfaces, can be stored on a register 403, such as a RAM or ROM. The comparison of the actual signal and the optimum setting will produce an error signal. The error signal can be passed through an absolute value generator 405 to ensure a positive value. The signal will then be forwarded to a energy storage device 407, such as a capacitor. If the signal is sufficient to cross the storage device, the signal will be passed through to the audible device 409. If the signal is not sufficient, it will simply be delivered back to the detecting sensor for continual monitoring. Audible devices 409 include speakers and earphone devices. Even if the signal is delivered to the audible device 409, a signal is sent to allow for continual monitoring.

Having described embodiments of the present system with reference to the accompanying drawings, it is to be understood that the present system is not limited to the precise embodiments, and that various changes and modifications may be effected therein by one having ordinary skill in the art without departing from the scope or spirit as defined in the appended claims.

In interpreting the appended claims, it should be understood that:

a) the word “comprising” does not exclude the presence of other elements or acts than those listed in the given claim;
b) the word “a” or “an” preceding an element does not exclude the presence of a plurality of such elements;
c) any reference signs in the claims do not limit their scope;
d) any of the disclosed devices or portions thereof may be combined together or separated into further portions unless specifically stated otherwise; and

e) no specific sequence of acts or steps is intended to be required unless specifically indicated.

The invention claimed is:

1. A method for preventing back pain, comprising the steps of:

   a) attaching a spine monitoring device to a user;
   b) setting said device by inputting a most suitable spinal condition or position during work periods;
   c) detecting a change in the spine to said user, wherein said change is forward flexion;
   d) determining whether said change is sufficient to cause a negative effect on spine;
   e) if change is sufficient, then steps a)-b),
      a) transmitting a signal to said user, and
      b) adjusting the spine of said user;
   and
   c) continuing to monitor said user’s spine, wherein said change is sufficient when said change is more than around +/-5% of said most suitable condition.

2. The method for preventing back pain of claim 1, wherein attaching said spine monitoring device occurs at said user’s ear.

3. The method of preventing back pain of claim 1, wherein said condition or position includes spine angle, pressure placed upon the spine, force on the spine, acceleration by which the spine changes said angle, or velocity by which the spine changes.

4. The method for preventing back pain of claim 1, wherein setting said device occurs via user interfaces.

5. The method of preventing back pain of claim 1, wherein transmitting said signal comprises transmitting an audible signal, visual signal, or sensory signal.

6. The method of preventing back pain of claim 1, wherein said negative effect can be selected from the group consisting of neck pain, back pain, spinal disk injury, spinal inflammation, and sciatica.
