Abstract— Demosaicing and compression are generally performed sequentially in most digital cameras. Recent reports show that the compression-first scheme outperforms the conventional demosaicing-first scheme in terms of image quality and complexity. In this paper, an efficient lossless compression scheme for Bayer images is presented. It exploits a context matching technique to rank the neighboring pixels for predicting a pixel. Besides, an adaptive color difference estimation scheme is also proposed to remove the spectral redundancy. Simulation results show that the proposed algorithm can achieve a better compression performance as compared with the existing lossless CFA image coding methods.

Index Terms—Image Compression, Color Filter Array, Cameras

I. INTRODUCTION

Most digital cameras use a single image sensor to capture scene images. In these cameras, Bayer color filter array (CFA) [1], as shown in Fig. 1, is usually coated over a sensor to record only one of the three chromatic components at each pixel location. In general, a CFA image is first interpolated via a demosaicing process [2-5] to form a full color image and then compressed for storage. Fig. 2a shows the workflow of this imaging chain.

Recently, some reports [6,7] indicated that such a demosaicing-first scheme was inefficient as the demosaicing process introduced redundancy which should eventually be removed in the compression step. As a result, an alternative approach [6,7] which carries out compression before demosaicing as shown in Fig. 2b has been proposed lately. Under this new strategy, digital camera can have a simpler design and lower power consumption is required as the computationally heavy processes like demosaicing can be carried out in an offline powerful personal computer. This motivates the demand of CFA image compression techniques.

II. CONTEXT MATCHING BASED PREDICTION

The proposed prediction scheme handles the green plane and the non-green planes separately in a raster scan manner. It reorders the neighboring samples such that the one has higher context similarity to that of the current sample will contribute more to the current prediction.

Fig. 3 – Positions of the pixels included in the candidate set of (a) a green sample and (b) a red/blue sample
Let us consider the prediction on the green plane first. Assume that we are now processing a particular green sample \( g(i,j) \) as shown in Fig 3a. The four nearest neighboring green samples of \( g(i,j) \) form a candidate set \( \Phi_{g(i,j)} = \{ g(i,j-2), g(i-1,j-1), g(i-2,j), g(i-1,j+1) \} \). The candidates are ranked by comparing their support regions (i.e. context) with that of sample \( g(i,j) \). The support region of a green sample at position \((i,j)\), \( S_{g(i,j)} \), is defined as shown in Fig. 4a. In formulation, we have \( S_{g(i,j)} = \{ (i-2,j), (i-1,j-1), (i-2,j-1), (i-1,j+1) \} \). The matching extent of the support regions of \( g(i,j) \) and \( g(m,n) \) for \( g(m,n) \in \Phi_{g(i,j)} \) is then measured by

\[
D(S_{g(i,j)}), S_{g(m,n)}) = |g(i,j-2) - g(m,n-2)| + |g(i-1,j-1) - g(m-1,n-1)| + |g(i-2,j) - g(m-2,n)| + |g(i-1,j+1) - g(m-1,n+1)|
\]

(1)

Let \( g(m,n) \in \Phi_{g(i,j)} \) for \( k=1,2,3,4 \) be the 4 ranked candidates of sample \( g(i,j) \) such that \( D(S_{g(i,j)}), S_{g(m,n)}) \leq D(S_{g(i,j)}), S_{g(m',n')} \) for \( 1 \leq k < 4 \). The value of sample \( g(i,j) \) can then be predicted with a prediction filter as

\[
\hat{g}(i,j) = \text{round} \left( \sum_{k=1}^{4} w_k g(m_k,n_k) \right)
\]

(2)

where \( w_k \) for \( k=1,2,3,4 \) are weight coefficients. In our study, \( w_k \)'s are obtained by quantizing the training result derived by linear regression with a set of training images covering half of the test images shown in Fig. 6. They are quantized to reduce the realization effort of eqn. (2). After all, the coefficients of the prediction filter used to obtain the result presented in this paper are \( \{ w_1, w_2, w_3, w_4 \} = \{ 5/8, 2/8, 1/8, 0 \} \) and the predicted green sample is given by

\[
\hat{g}(i,j) = \text{round} \left( \frac{4g(m_n, n_i) + 2g(m_{n_i}, n_j) + g(m_{n_i}, n_{j+1}) + g(m_{n_i}, n_{j-1})}{8} \right)
\]

(3)

As for the case when the sample being processed is a red or blue sample, the prediction is carried out in the color difference domain instead of the green color plane as before. Let \( d(m,n) \) be the green-red (or green-blue) color difference value of a non-green sample \( c(m,n) \). Its determination will be discussed in detail in Section III, where an adaptive color difference estimation method is proposed.

For any non-green sample \( c(i,j) \), its candidate set becomes \( \Phi_{c(i,j)} = \{ d(i,j-2), d(i-2,j-2), d(i-2,j), d(i-1,j+2) \} \) and its support region (context) is defined as \( S_{c(i,j)} = \{ (i-1,j-1), (i-1,j), (i+1,j) \} \) as shown in Fig. 3b and Fig. 4b, respectively.

The prediction for a non-green sample is carried out in color difference domain. Specifically, the predicted color difference value of sample \( c(i,j) \) is given by

\[
\hat{d}(i,j) = \text{round} \left( \sum_{k=1}^{4} w_k d(m_k,n_k) \right)
\]

(4)

where \( w_k \) and \( d(m_k,n_k) \) are, respectively, the \( k \)th predictor coefficient and the \( k \)th ranked candidate in \( D(S_{c(i,j)}), S_{c(m,n)}) \) such that \( D(S_{c(i,j)}), S_{c(m,n)}) \leq D(S_{c(i,j)}), S_{c(m',n')} \) for \( 1 \leq k < 4 \), where

\[
D(S_{c(i,j)}), S_{c(m,n)}) = |d(i,j-2) - d(m,n-2)| + |d(i-2,j-2) - d(m-2,n-2)| + |d(i-2,j) - d(m-2,n)| + |d(i-1,j+2) - d(m-1,n+2)|
\]

(5)

Again, \( w_k \) are trained with the same set of training images used to train the predictor coefficients in eqn. (2). For the compression results reported in this paper, the predictor used for the color difference prediction is

\[
\hat{d}(i,j) = \text{round} \left( \frac{4d(m_n, n_j) + 2d(m_{n_i}, n_j) + d(m_{n_i}, n_{j+1}) + d(m_{n_i}, n_{j-1})}{8} \right)
\]

(6)

In the proposed compression scheme, all green, red and blue pixels are encoded respectively in a raster scan manner. The four samples used for predicting sample \( g(i,j) \) in eqn. (2) are \( g(i,j) \)'s closest processed neighboring samples of the same color. They have the highest correlation to \( g(i,j) \) in different directions and hence can provide a good prediction result even in an edge region. A similar argument applies to explain why \( \Phi_{g(i,j)} \) is used in eqn. (4) to handle blue/red samples.

As for the support regions, no matter the concerned sample is green or not, as shown in Fig. 4, their supports are defined based on their four closest known green samples. This is because the green channel has a double sampling rate as compared with the other channels in a CFA image and hence provides a more reliable context for matching. In the proposed scheme, as green samples are encoded first in raster sequence, all green samples are known in the decoder and hence the support of a non-green sample can be non-causal while the support of a green sample has to be causal. This non-causal support tightly and completely encloses its sample of interest. It models image features such as intensity gradient, edge orientation and textures better such that more accurate support matching can be achieved.

III. ADAPTIVE COLOR DIFFERENCE ESTIMATION

When compressing the non-green color plane, color differences are exploited to remove the spectral dependency. Let \( c(m,n) \) be the intensity value of the available color (either red or blue) at a non-green sampling position \( (m,n) \). The green-red (green-blue) color difference of pixel \( (m,n) \), \( d(m,n) \), is obtained by

\[
d(m,n) = \hat{g}(m,n) - c(m,n)
\]

(7)

where \( \hat{g}(m,n) \) represents an estimate of the missing green component at position \( (m,n) \). In the proposed estimation, \( \hat{g}(m,n) \) is adaptively determined according to the horizontal gradient \( \partial H \) and the vertical gradient \( \partial V \) at \( (m,n) \) as follows.

\[
\hat{g}(m,n) = \text{round} \left( \frac{\partial H \times G_H + \partial V \times G_V}{\partial H + \partial V} \right)
\]

(8)

where \( G_H = \frac{g(m,n-1) + g(m,n+1)}{2} \) and \( G_V = \frac{g(m-1,n) + g(m+1,n)}{2} \).
donate, respectively, the preliminary green estimates obtained by linearly interpolating the adjacent green samples horizontally and vertically. Note that, in eqn.(8), the missing green value is determined in such a way that a preliminary estimate contributes less if the gradient in the corresponding direction is larger. The weighing mechanism automatically directs the estimation process along an edge if there is.

Gradients $\delta H$ and $\delta V$ are determined by averaging all local green gradients in the same direction within a 5×5 window as

$$\delta H = \frac{1}{5} \sum_{(p,q)\in 5\times5} g(p,q) - g(p,q + 2)$$

and

$$\delta V = \frac{1}{5} \sum_{(p,q)\in 5\times5} g(p,q) - g(p + 2,q).$$

(9)

### IV. PROPOSED COMPRESSION SCHEME

Fig. 5 shows the proposed compression scheme. In the encoding phase, a CFA image is first divided into 2 sub-images: a green sub-image which contains all green samples of a CFA image and a non-green sub-image which holds the rest samples. The green sub-image is coded first and the non-green sub-image follows based on the green sub-image as a reference.

![CFA Image](image-url)

Fig. 5 – Structure of the proposed compression scheme: (a) encoder and (b) decoder

To code a sub-image, the sub-image is raster-scanned and each pixel is predicted with its 4 neighboring pixels by using context matching based prediction (CMBP), the prediction scheme proposed in Section II. Its prediction error, say $e(i,j)$, is given by

$$e(i,j) = \begin{cases} \hat{g}(i,j) - g(i,j) & \text{when } (i,j) \text{ is in green sub-image} \\ \hat{d}(i,j) - d(i,j) & \text{when } (i,j) \text{ is in non-green sub-image} \end{cases}$$

(10)

where $g(i,j)$ is the real green sample value (if it exists) and $d(i,j)$ is the color difference of pixel $(i,j)$ estimated by the method described in Section III. $\hat{g}(i,j)$ and $\hat{d}(i,j)$, respectively, represent the predicted value of $g(i,j)$ and the predicted value of $d(i,j)$. The error residue $e(i,j)$ is then mapped to a non-negative integer as follows to reshape its value distribution from a Laplacian one to an exponential one for Rice code.

$$E(i,j) = \begin{cases} 2e(i,j) & \text{if } e(i,j) \geq 0 \\ -2e(i,j) - 1 & \text{otherwise} \end{cases}$$

(11)

The Rice code is employed in the proposed scheme because of its simplicity and its efficiency in handling exponentially distributed sources. In Rice code, the mapped residue $E(i,j)$ is compressed by splitting it into a quotient $Q$ and a remainder $R = E(i,j)mod 2^P$ with a positive integer $P = 2^p$ called Rice parameter, where $k \leq 0$. The quotient and the remainder are then saved for storage or transmission. The length of the codeword used for representing $E(i,j)$ is given by

$$L(E(i,j)) = \left\lfloor \frac{E(i,j)}{\lambda} \right\rfloor + 1 + \log_2 \lambda.$$  

(12)

Parameter $\lambda$ is critical to the compression performance of Rice code as it determines the code length of $E(i,j)$. In the proposed scheme, parameter $\lambda$ is determined by $\theta(i,j)$, a local information index of pixel $(i,j)$ defined as

$$\theta(i,j) = E(m_1,n_1) + E(m_2,n_2) + E(m_3,n_3) + E(m_4,n_4)$$

(13)

where $E(m_k,n_k)$ for $k=1,2,3,4$ are the corresponding mapped prediction errors of the four ranked candidates in $\Phi_{E(i,j)}$ (or $\Phi_{E(i,j)}$ depends on whether $(i,j)$ is a green sample) acquired during CMBP. As the residue plane still contains certain amount of pixel correlation, applying the ranked local information to compute $\theta(i,j)$ can better model residue $E(i,j)$ for the estimation of parameter $\lambda$.

$\theta(i,j)$ can then be classified into a few of groups, and the corresponding parameter $\lambda$ for $E(i,j)$ is determined as

$$\lambda(i,j) = 2^p, \quad p = \arg \max \frac{\theta(i,j)}{b_i}$$

(14)

In (14), $b_i$ are the boundaries of a $K$-class classifier $C = \{0 \equiv c_0 < c_1 < c_2 < \cdots < c_k < +\infty\}$ for $z=1,2,\cdot\cdot\cdot,K$. They are determined by minimizing the total code length for the sub-image using dynamic programming, i.e.

$$C_{opt} = \min_{C} \sum_{(i,j) \in \text{sub-image}} L(E(i,j)) \cdot \lambda(i,j)$$

(15)

where $\zeta$ donates the set of all pixels in a sub-image.

As it is not practical to compute $b_i$ on the fly, they are obtained by offline training. With the same set of training images mentioned in Section II, classifiers $C_{opt} = \{0, 1, 8, 21, 43, 99, 251, +\infty\}$ and $C_{opt} = \{0, 1, 8, 21, 47, 118, 326, 574, +\infty\}$ were obtained and used for coding the green sub-image and the non-green sub-image respectively in our simulations.

The decoding process is just the reserve process of encoding. The green sub-image is decoded first and then the non-green sub-image is decoded with the decoded green sub-image as a reference. After the CFA image is reconstructed by combining the two sub-images.

### V. COMPRESSION PERFORMANCE

Simulations were carried out to evaluate the compression performance of the proposed scheme. Twenty-four 24-bit color images of size 512×768 each as shown in Fig. 6 were Bayer sub-sampled to form a set of 8-bit testing CFA images. They were then directly coded by the proposed compression scheme. Some representative lossless compression algorithms such as JPEG-LS [9], JPEG 2000 (lossless mode) [10] and LCMI [11] were also evaluated for comparisons.
Table 1 lists the output bit-rates of the CFA images achieved by various algorithms. It clearly shows that the proposed scheme outperforms all other evaluated methods in all testing images. Especially for the images which contain many fine textures such as images 5, 7, 8, 13, 20 and 24, the bit-rates achieved by the proposed scheme are at least 0.32bpp lower than the corresponding bit-rates achieved by LCMI, which is the method offers the second best compression performance. On average, the proposed scheme yields a bit-rate as low as 4.64bpp. It is, respectively, around 1.26, 0.37 and 0.25 bpp lower than those achieved by JPEG-LS, JPEG2000 and LCMI.

Table 2 – Achieved bit-rates for coding non-green planes with algorithms in terms of bits per pixel (bpp)

Table 1 – Achieved bit-rates of various lossless compression JPEG-LS, JPEG2000 and LCMI.

As a green pixel estimation method is proposed and used when compressing the non-green sub-image in color difference domain, a simulation was also carried out to evaluate its performance. For comparison, some other estimation methods such as bilinear interpolation [4] (BI), edge sensing interpolation [5] (ESI) and adaptive directional interpolation [2] (ADI) were also evaluated. To provide a clear demonstration, only the non-green sub-image was coded in this simulation.

Table 2 reveals the average bit rates of the outputs achieved by various estimation algorithms. It shows that the proposed adaptive estimation method yields the best compression performance among the evaluated estimation schemes. On average, the proposed estimation method achieves a bit-rate of 4.51bpp which is around 0.08 bpp lower than that achieved by BI.

Table 2 – Achieved bit-rates (bpp) for coding non-green planes with algorithms in terms of bits per pixel (bpp)

VI. CONCLUSION

In this paper, a lossless compression scheme for Bayer images is proposed. This scheme separates a CFA image into a green sub-image and a non-green sub-image and then encodes them separately with prediction coding. The prediction is carried out in the intensity domain for the green sub-image while it is carried out in the color difference domain for the non-green sub-image. In both cases, a context matching technique is used to rank the neighboring pixels of a pixel for predicting the existing sample value of the pixel. The prediction residues of the two sub-images are then separately encoded with Rice code adaptively.

Experimental results show that the proposed compression scheme can efficiently and effectively decorrelate the data dependency in both spatial and color spectral domains. Consequently, it provides the best average compression ratio as compared with the latest lossless Bayer image compression schemes.
