1 **Abstract**

2 **Background/aims:** Quantitative and objective technique to assess radiation-induced

3 tissue fibrosis is important for clinicians to estimate the efficiency of radiotherapeutic

4 schemes. It has been widely reported that ultrasonic properties are sensitive to

5 changes of acoustic scatterers in biological tissues. Therefore, measurement of

6 ultrasonic properties may serve as a potential assessment technique for irradiated

7 skins. The aim of the present study is to investigate the reliability of such

8 measurement so as to evaluate its potentials for future clinical applications.

9 **Methods:** Ultrasonic parameters including attenuation slope (β), integrated

10 attenuation (IA) and integrated backscatter (IBS) were measured for the frequency

11 range of 10 to 25 MHz from echographic signals of the forearm and neck dermis of 20

12 normal subjects *in vivo*. The intra- and inter-rater reliability of measurement was

13 assessed in 10 normal subjects using intra-class correlation coefficients (ICC) and

14 Bland-Altman test.

15 **Results:** The intra- and inter-rater measurement was demonstrated to be reliable as

16 indicated by high ICC values generally larger than 0.80. In addition, the ultrasonic

17 parameters could successfully differentiate the skins in the neck and forearm regions.

18 **Conclusion:** The measurement provided reliable information on the ultrasonic

19 properties of the skins and could be potentially applied to comparative clinical trials

20 to assess the late effects of radiotherapy on skins.

21

22 **Keywords:** radiotherapy – skin – fibrosis – high frequency ultrasound – ultrasonic

23 tissue characterization – ultrasonic properties – reliability.

1   **Introduction**

2   Fibrosis is a common late side effect of radiotherapy. Assessment and

3   quantification of the severity of tissue fibrosis are important in determining the curing

4   ratio of different radiotherapeutic regimes or assessing the efficiency of various anti-

5   fibrotic medicines (1). Although some standard protocols such as the LENT/SOMA

6   scoring system have been established to assess the degrees of late radiation toxicities

7   (1), clinical practice is still mainly limited to hand palpation. Quantitative and

8   objective methods have not been intensively investigated for this purpose.

9   Being noninvasive and inexpensive, high-frequency (larger than 10 MHz)

10   ultrasound has been successfully introduced in dermatology to detect the delicate skin

11   structures and lesions in the last two decades (2-4). Applications of ultrasound

12   reported in dermatology generally include two kinds of measurement, i.e., skin

13   thickness and echogenicity. Skin thickness can be directly measured from the

14   ultrasound images, while a common way to calculate the echogenicity is based on

15   counting the number of pixels with a certain range of intensity values in images (5).

16   This method has been used for the study of skin reactions induced by therapeutic or

17   accidental radiation and high frequency ultrasonic imaging is recommended as a

18   reliable tool to assess the irradiated effects on the skin (6, 7).

19   On the other hand, it has been widely reported that ultrasonic propagation

20   properties are sensitive to the structural, compositional and pathological changes of

21   acoustic scatterers in biological tissues (8). The propagation parameters are extracted

22   from the radiofrequency (RF) signals, thus capable of providing new information on

23   tissue conditions, such as frequency-dependent attenuation, in addition to the

24   envelope signals used in the conventional ultrasonic imaging. Previous studies had

25   showed that it was potential to monitor the skin changes induced by healing process

1 or patch-test (9, 10). We have successfully used an ultrasound indentation technique

2 to measure the mechanical properties of neck tissues with radiotherapy-induced

3 fibrosis (11-13). During the study, we noted that the ultrasound signals scattered from

4 the skin and subcutaneous tissues were different for subjects with different degrees of

5 tissue fibrosis. In this study, we aimed to test the reliability of the high frequency

6 ultrasound measurement for the skin assessment so as to prepare for the future clinical

7 applications of this technique.

8 There had been some reports on the reliability of measurement of skin ultrasonic

9 parameters in literature. For example, Guittet et al. (14) reported a coefficient of

10 variation of 12% for the attenuation slope of skin; Fournier et al. (15) reported a

11 standardized coefficient of variation of less than 20% for the backscatter spectral

12 parameters of skin. However, it is difficult to transfer the measurement precision from

13 one system to another due to the use of different devices and detection techniques.

14 Accordingly, we investigated the reliability of measurement of ultrasonic parameters

15 including attenuation slope, integrated attenuation and integrated backscatter in the

16 skin *in vivo* using a 20 MHz ultrasonic imaging system. Intra-class correlation

17 coefficients (ICC) and Bland-Altman test were used to estimate the reliability with

18 respect to the intra- and inter-rater operations.

19

20 **Methods**

21 **Data acquisition system**

22 The system used for data collection was a 20 MHz ultrasonic imaging system

23 developed for skin applications (Ultrasons Technologies, Tours, France). A handheld

24 cylindrical probe, inside which there was a focused mono-element transducer, was

1   used to collect echographic RF signals. Using the reflection signals from a planar steel

2   plate immersed in a water tank, the measured central frequency of the transducer was

3   15 MHz with a -3 dB bandwidth of 10~25 MHz. A rigid removable cover with a flat

4   membrane of 15 μm in thickness was tightly attached to the end of the probe to allow

5   the ultrasound propagating through and to form the chamber for the acoustic coupling

6   medium. The ultrasonic beam focused at approximately 2 mm beyond the membrane.

7   Water was used to fill the cavity formed by the cover and the transducer. The

8   transducer was translated linearly in the probe during operation. The contact area

9   between the cover and the skin was small with a dimension of 11×19 mm^2 and the

10   effective width of image was 6 mm in the lateral direction. Each collected image

11   provided a set of 256 RF signal lines, with 1024 data points in each line sampled at

12   100 MHz. The lateral resolution of the transducer was approximately 0.2 mm,

13   therefore producing totally 28 independent lines per image, which were used for

14   spatial averaging. In the studied region of interest (from 0.3 to 1.3 mm beneath the

15   skin surface), we found that the average Pearson correlation for two adjacent lines

16   was 0.24 ± 0.04 in the forearms of 5 normal subjects, indicating good independence

17   for the signals.

18   **Extraction of ultrasonic parameters**

19   In this study, the skin was assumed to be composed of epidermis and dermis with

20   a total thickness larger than 1.3 mm and the speed of sound was assumed to be 1.58

21   mm/μs throughout the whole skin layer (16). The ultrasonic propagation parameters

22   were extracted from the spatially averaged RF signals using a multi-narrowband

23   algorithm (17). The reference signals from a planar steel plate were collected in order

24   to correct the system-dependent effects. The detailed procedure was described as

25   follow.

1   *Attenuation slope (β) and integrated attenuation (IA).* A Hamming-window with a

2   length of 50 points (0.40 mm) was used to gate the original temporal signal from the

3   point 40 (0.32 mm) after the skin entry echo to the point 165 (1.30 mm) with 50%

4   overlapping between two consecutive windows. This region was defined as the region

5   of interest (ROI) as shown in Fig 1.a and 1.b. The skin entry echo was detected

6   automatically in a custom-designed program based on the sudden change of the signal

7   energy. According to the window selection principle, totally six short signals were

8   obtained from each scanned line. Fast Fourier transform (FFT) was used to obtain the

9   power spectra of the short signals after they were zero-padded to 512 points. The

10   power spectra from the 28 independent lines were then averaged before they were

11   divided by those of the corresponding reference signals to correct the system-

12   dependent effects. The spectra of reference signals were obtained by applying the

13   same window to the signals completely reflected from the steel plate in water at the

14   same distance as the selected short signals. The signal lines which had saturated in the

15   ROIs were excluded in the averaging procedure in order to avoid the contamination of

16   spectra induced by the saturation. After correction, the six power spectra were

17   logarithmically transformed (Fig 1.c) and regressed by the propagation distances of

18   ROIs. Based on a commonly used hypothesis that the skin backscatter was

19   homogeneous in all selected skin depths (18), the attenuation coefficients $\alpha(f)$ (unit:

20   dB/mm) in 10~25 MHz were obtained (Fig 1.d). It was assumed that $\alpha(f)$ was

21   linearly dependent on frequency, i.e.:

22   $$\alpha(f) = \beta \cdot f + \alpha_0 \qquad (1)$$

23   where β (unit: dB/mm/MHz) is the attenuation slope and α_0 (unit: dB/mm) is the

24   intercept at zero frequency. β was then calculated from the regression of $\alpha(f_i)$ to

1   frequency f_i obtained from the experiment. The integrated attenuation (IA , unit:

2   dB/mm) was defined as:

3    $$\mathrm{IA} \equiv \frac{1}{f_h - f_l} \int_{f_l}^{f_h} \alpha(f)df \qquad (2)$$

4   where $f_l = 10\,\mathrm{MHz}$ and $f_h = 25\,\mathrm{MHz}$, are the lower and upper bounds of the -3 dB

5   bandwidth of the transducer.

6   *Integrated backscatter (IBS).* The signal in the ROI from the point 40 to 165 (0.32

7   to 1.30 mm) after the skin entry was used for the calculation of the backscatter

8   coefficient. The temporal signals were gated using a Hamming-window (125 points)

9   and zero-padded to 512 points before FFT transformation to power spectra. The

10   power spectra of the independent lines of each image were averaged and divided by

11   those of the reference signals using the same Hamming-window. The system-

12   corrected spectra were then logarithmically transformed to obtain the backscatter

13   spectra $B(f)$. The integrated backscatter (IBS, unit: dB) was then defined similarly to

14   that of IA:

15   $$\mathrm{IBS} \equiv \frac{1}{f_h - f_l} \int_{f_l}^{f_h} B(f)df \qquad (3)$$

16   where f_h and f_l are the range of the -3 dB bandwidth as in Eq. (2). It should be

17   noted that IBS was not corrected by attenuation of the skin-film-water interface and

18   the partial skin on top of the selected region. This parameter represented an average

19   level of backscatter of the selected skin.

20   **Tests of reliability and experiments on normal subjects**

21   The *in-vivo* study was conducted for 20 normal subjects (age: 27 ± 3 yrs) under

22   room temperature at approximately 25°C. In order to test the intra-rater reliability of

1   this measurement, tests on 10 normal subjects were conducted by the first operator

2   twice with a time lapse of one week. To test the inter-rater reliability, the

3   measurement was also conducted by a second operator during the first data collection

4   by the first operator. The two operators were both working in the ultrasound field and

5   knew well the principles and details of the measurement. The selected testing sites

6   were located on the palmar side (3 cm away from the radiocarpal joint and along the

7   media nerve) and the dorsal side (in the middle portion of the forearm and 2 cm

8   proximal to the ulnar styloid) of the distal forearm and also on both sides (5 cm below

9   the mastoid bone) of the neck. We were interested in neck sites because we would

10   recruit patients who had skin fibrosis in the neck due to radiotherapeutic radiation in

11   future studies. The forearm testing sites served as the comparative parts of the neck

12   sites in the same subject. The study was approved by the Research Ethics Committee

13   of the investigators' affiliated institutions and written informed consent was obtained

14   from each subject at recruitment.

15   The subjects were asked to be seated when the forearm sites were tested, and to lie

16   on their sides when the neck sites were tested, both in a relaxing state. The probe was

17   applied to the skin surface using a very small pressure in order to avoid changing the

18   ultrasonic properties inconsistently by the probe pressure (15). Water was used as

19   coupling medium between the probe and skin. Three repeated tests were conducted at

20   each testing site and the averaged results of the three tests were used to represent the

21   ultrasonic properties at that site.

22   **Data analysis methods**

23   The intraclass correlation coefficient (ICC) and the Bland-Altman test (19) were

24   used to estimate the reliability of the ultrasound measurement. ICC represents the

25   proportional contribution of variance of interest with respect to total variance

1 (variance of interest + measurement error). In our study, intra-rater and intra-rater

2 reliability was respectively assessed by ICC(1,3) and ICC(3,3), the detailed meaning

3 of which was described in (19). Bland-Altman test is used to analyze the individual

4 difference of two repeated measurements. The reliability coefficient, as defined to be

5 two standard deviations of the individual difference by assuming the mean difference

6 to be zero, stands for the range of individual difference observed for 95% pairs of

7 measurements (19). ICC and Bland-Altman test were widely used to quantify the

8 reliability of measurement for continuous data.

9   The ultrasonic parameters in normal subjects were compared using the paired t-

10 test between two sites in the forearm, in the neck, and between the forearm and neck

11 regions. The parameters of two testing sites in the forearm or neck were pooled to be

12 mean values of the forearm or neck if no significant difference was found in the two

13 regions. All the statistical analyses were conducted by using the statistical software

14 SPSS (SPSS Inc., Chicago, IL, USA). A comparison with $P < 0.05$ was used to

15 indicate a significant difference.

16

17 **Results**

18   Table 1 shows the results of ICC and their 95% confidence intervals for the intra-

19 and inter-rater measurement. All ICCs were larger than 0.80, which indicated a high

20 reliability. Table 2 shows the results of Bland-Altman test for the individual

21 difference of intra- and inter-rater operations. 95% CIs of the individual difference of

22 ultrasonic properties included zero value, indicating the intra- and inter-rater

23 measurement was unbiased.

24   Fig 2 shows the typical images obtained from the forearm and neck regions of a

25 normal subject. It was consistently observed from these images that the neck skin in

1   the dermal region was darker in comparison with the forearm skin. Fig 3 shows a

2   summary of the ultrasonic properties measured from the 20 normal subjects. For all

3   the parameters, no significant difference was demonstrated between two sites of the

4   forearm ($P > 0.05$) and between two sides of the neck ($P > 0.05$). Therefore, data of

5   the two sites within each region were pooled for the subsequent data analyses. For the

6   attenuation coefficients, a linear relationship versus frequency with a regressed

7   correlation coefficient larger than 0.90 could be generally obtained (Fig 1.d), showing

8   that a linear relationship was good enough to describe the frequency-dependent

9   characteristics. In the neck and forearm regions of the normal subjects, β was 0.328

10    $\pm$ 0.037 and 0.375 $\pm$ 0.037 dB/mm/MHz ($P < 0.001$), IA was 2.17 $\pm$ 1.90 and 0.58 $\pm$

11   1.34 dB/mm ($P = 0.001$), and IBS was -33.55 ± 3.12 and -31.42 ± 2.44 dB ($P <$

12   0.001), respectively. The finding of a smaller IBS in the neck region was consistent

13   with the observation of the dermal echogenicity in the images.

14

15   **Discussion**

16   A hand-held 20 MHz ultrasound probe was introduced in the current study to

17   measure the ultrasonic propagation properties of skin *in vivo*. The reliability of intra-

18   and inter-rater measurement was investigated in order to assess its potential use in

19   clinical trials. Tests for 20 normal subjects were conducted and results were reported.

20   The results showed that all ICCs for the intra- and inter-rater tests were larger than

21   0.80, indicating that the measurement was highly reliable (20). It means that the

22   influence of day-to-day and rater-to-rater variations were limited in the given test

23   conditions. However, it should be noted that in order to maintain such high test

24   reliability, basic training on the test operations for a rater was necessary before the

25   rater could conducted the corresponding research. The key factors in operating the

1   probe included gentle contact pressure, accurate probe orientation and good coupling

2   between the probe and skin. If these conditions could be guaranteed, the measurement

3   could be highly reliable and this ultrasound method was potential to be applied in

4   clinical trials to assess the skin effects induced by radiotherapy.

5   The acoustic properties of the skins in the forearm and neck were demonstrated to

6   be significantly different by the ultrasonic measurement. The difference was regarded

7   as a reflection of the anatomic distinction of the skins in these two regions. Raju et al.

8   (18) reported a larger β in the dermis of fingertip in comparison with that of two

9   locations in the forearm. They attributed the difference to the potential variations of

10   skin tension and collagen structure between the fingertip and forearm skins. A

11   significantly smaller value of *IBS* was found in the neck than forearm region in the

12   current study. Relevant study about skin echogenicity by Pellacani and Seidenari (21)

13   demonstrated that the facial skin was much less reflective than the forearm skin. Thus

14   the current findings were not contradictive to their results if the neck skin was

15   assumed to be more similar to the facial skin in terms of ultrasonic scattering. Further

16   investigations are required to explain the exact reason for the differences between the

17   two regions.

18

19   **Conclusion**

20   The reliability of the current measurement of the ultrasonic properties was high

21   with ICCs larger than 0.80. The ultrasonic parameters could discriminate the skins in

22   the forearm and neck regions in the normal subjects. Considering that the operation of

23   the current method was reliable, easy, and non-invasive, we expected that it would be

24   potentially useful for the comparative clinical trials to assess the late effects of

25   radiotherapy to the skin and future research towards this direction is being conducted.

6   **Totally n = 40 measurements were used for computation of each test. $\bar{d}$ is the mean difference**
7   **of the second measurement to the first measurement for the intra-rater operation, or the**
8   **measurement of the second rater to that of the first rater for the inter-rater operation; $SD_{\bar{d}}$ is**
9   **the SD of the mean difference calculated from the original data; $SE_{\bar{d}}$ is the standard error of the**
10   **difference, calculated as $SE_{\bar{d}} = SD_{\bar{d}} / \sqrt{n}$; 95% CI of $\bar{d}$ is the 95% CI for the mean difference,**
11   **being defined as $\bar{d} \pm t_{n-1} \cdot SE_{\bar{d}}$, where t is the critical value of t-distribution at $p = 0.05$.**
12   **Reliability coefficient is calculated to be $2\sqrt{\sum_{i=1}^{n} d_i^2 / n}$, where d_i is the individual difference for**
13   **test i among a total of n measurements.**
