1

2 Introduction

Whole-body vibration has attracted much interest in rehabilitation in the past decade. In wholebody vibration treatment, vibration stimuli with combinations of different amplitudes and
frequencies are delivered to the body from the feet which make contact with the vibration
platform. Typically, static or/and dynamic exercises are performed while standing on the wholebody vibration platform.¹

8

Vibratory stimulus has been shown to modulate Ia afferent-motoneuron synaptic transmission by 9 causing presynaptic inhibition.² Recent studies have found that H-reflex was depressed during 10 and after whole-body vibration in young healthy adult population.³⁻⁶ Measured by transcranial 11 magnetic stimulation, whole-body vibration was shown to increase the excitability of the 12 corticomotor pathway and intracortical inhibition while decreasing intracortical facilitation.⁷ In 13 addition, there is some evidence that whole-body vibration could increase temperature and blood 14 flow in both skin and lower limb muscles.⁸⁻¹² These changes in thermoregulation and muscle 15 perfusion may lead to alterations in viscoelastic properties of soft tissue¹² and may partially 16 explain the increase in flexibility of the lower extremities among athletes after whole-body 17 vibration.9, 13 18

19

The effects of whole-body vibration on reflex activity and mechanical properties of muscles may thus have therapeutic implications for people with central nervous system disorders, in which muscle spasticity is a common manifestation.¹⁴ The secondary problems stemming from muscle spasticity are diverse and may include reduced functional mobility and activity participation.^{15, 16} Hence, much research effort has been directed to determine effective treatment strategies to
 tackle the issue of spasticity in central nervous system disorders.

3

The past decade saw considerable increase in research studies that investigated the influence of 4 5 whole-body vibration on muscle spasticity in people with central nervous system disorders. It is 6 thus timely to conduct a systematic review to examine the overall evidence, which can be used to guide clinical decision making. The primary objective of this systematic review was to examine 7 the effects of whole-body vibration on spasticity in people with central nervous system disorders. 8 9 The secondary objective was to examine whether the whole-body vibration-induced improvement in muscle spasticity, if present, was associated with changes in functional 10 performance. 11

12

13 Materials and Methods

14 *Research question*

This systematic review aimed to answer the following two questions. First, does whole-body 15 vibration therapy lead to better muscle spasticity outcomes compared with no vibration under the 16 17 same exercise condition, or other forms of intervention among individuals with central nervous system disorders? Second, is there a relationship between change in muscle spasticity and 18 19 improvement of functional level after whole-body vibration intervention? The PICO (P=Patients, 20 I=Intervention, C=Comparison, O=Outcomes) method was used to define the four major components of the research question:¹⁷ P=individuals with central nervous system disorders; 21 22 I=whole-body vibration; C=(1) comparison with no whole-body vibration under the same 23 exercise condition, and (2) comparison with other forms of physical activity/intervention;

O=muscle spasticity (primary outcome), and all measures of functional performance (secondary
 outcomes).

3

4 Study selection 5 The inclusion criteria for article were (1) randomized controlled trials that investigated the 6 effects of whole-body vibration in people whose primary diagnosis was a central nervous system 7 disorder; (2) the study had included at least one measurement related to muscle spasticity; (3)

8 published in English. Exclusion criteria were (1) studies that used focal vibration or

9 physioacoustic vibration as an intervention rather than whole-body vibration, or (2) animal

studies, or (3) reported in books, conference proceedings, theses or dissertations.

11

12 *Data sources and searches*

An extensive literature search was done using the following electronic databases: MEDLINE 13 (1950 to 31 August 2015), PubMED (until 24 August 2015), Cumulative Index to Nursing and 14 Allied Health Literature (CINAHL)(1982 to 24 August 2015), SPORTDiscus (1830 to 24 August 15 2015), PsychoINFO (1806 to 24 August 2015), Cochrane Library (1898 to 24 August 2015) and 16 17 Physiotherapy Evidence Database (PEDro) (until 24 August 2015). A combination of search terms pertaining to whole-body vibration therapy and central nervous system disorders (e.g., 18 cerebrovascular disease, cerebral palsy, multiple sclerosis, spinal cord injury, etc.) was generated 19 20 to identify potential studies. The specific search strategy for MEDLINE database is described in the Appendix. A similar search strategy was used for other database, with the exception of 21 22 PEDro in which the key word "vibration" was used in simple search. The search strategy and

search terms used were validated by a librarian in biological sciences and confirmed with the
 principal investigator.

3

Two well-trained researchers conducted the article search and screening independently. Any 4 5 disagreement was resolved by discussion with the principal investigator. Duplicate articles 6 generated by the different databases were removed using an electronic reference management tool RefWorks (Bethesda, MD, USA). The titles and abstracts of the articles were first screened 7 to eliminate the irrelevant studies. The full-text of the remaining articles was reviewed in detail 8 to determine the eligible ones. The reference list of each selected article was extensively checked 9 to identify other potential relevant studies. A forward search was conducted using Scopus on 30 10 August 2015 to identify all relevant articles that had referenced the selected articles. 11

12

13 Methodological quality assessment

The Physiotherapy Evidence Database (PEDro) scale was used to evaluate the scientific rigor of
the selected clinical trials (9-10=excellent, 6-8=good, 4-5=fair, and ≤4 =poor).¹⁸ It was
developed to assess both external validity (i.e. item 1 in PEDro scale, not considered in
calculation of total score) and internal validity (i.e. item 2-11) (Table 1, supplementary data
online). The PEDro score of these studies could be obtained by searching PEDro database except
Cheng et al.¹⁹ Therefore, this article was rated independently by two researchers who were
experienced with using the PEDro.

21

22 The Oxford Centre for Evidence-Based Medicine Levels of Evidence (2009) was used to

23 determine the level of evidence for each reviewed articles based on the study design and

methodological quality.¹⁷ For randomized controlled trials, level 1b indicated good-quality
(PEDro score ≥6 and sample size >50), while the level 2b indicated poor quality (PEDro score
<6 or sample size ≤50).²⁰ The evidence level of each study was determined independently by
two researchers who were familiar with the Oxford Centre for Evidence-Based Medicine Levels
of Evidence (2009), and any inconsistent results were resolved after discussion with the principal
investigator.

7

8 Quality of whole-body vibration reporting

It is important to clearly report the whole-body vibration protocol in order to facilitate clinical 9 application of scientific findings. Thus, the quality of whole-body vibration reporting was 10 assessed using the checklist adapted from the one endorsed by the International Society of 11 Musculoskeletal and Neuronal Interactions.²¹ There are 13 items in the original checklist related 12 to various aspects of the whole-body vibration protocols. In addition, we also added an item 13 related to the supervision received during the whole-body vibration exercise training, which may 14 have important impact on treatment outcomes.²² A score was given if the criterion described in a 15 particular item was fulfilled. The maximum possible score was 14 (table 2, supplementary data 16 17 online).

18

19 *Data synthesis and analysis*

Information about the key demographic characteristics of the participants, whole-body vibration
intervention protocols, and outcomes of each study was extracted. After reviewing the results of
the selected studies, it was decided that meta-analysis was not appropriate because only few
studies (<5) used the same outcome measures, and the treatment protocols also varied

substantially among the different studies. To estimate the size of the treatment effect for those
outcomes that yielded significant results, the standardized effect size (SES) with Hedges'
correction was computed (small SES= 0.2, medium= 0.5, large=0.8) based on the data provided
in the selected articles.^{23, 24} Kappa statistic was used to assess the degree of agreement between
the two researchers in selection and rating of the articles, using IBM SPSS software (version
20.0, IBM, Armonk, NY, USA).

7

8 **Results**

A total of 296 records were identified after duplicates were removed. Of these, nine articles met
our selection criteria (Figure 1). Excellent inter-rater agreement for article selection was found at
the stage of title and abstract screening (kappa=0.830, p<0.001), as well as full text screening
(kappa=0.856, p<0.001).

13

14 *Study population*

Three trials studied the effects of whole-body vibration on muscle tone in cerebral palsy,^{19, 25, 26} one in multiple sclerosis,²⁷ one in spinocerebellar ataxia,²⁸ and four in stroke.²⁹⁻³² A total of 266 subjects with central nervous system disorders were involved, with the mean age ranging from 9.8 to 69.7 years. The key characteristics of participants in each study are summarized in table 3.

20 Whole-body vibration training protocol

The summary of whole-body vibration training protocols adopted in various studies is provided
 in table 4 (supplementary data online). Six studies used synchronous (vertical) vibrations,<sup>19, 27, 29 ³² one used side-alternating vibrations,²⁶ and one utilized stochastic vibrations.²⁸ One study did
</sup>

not report the type of vibration used.²⁵ The frequency and amplitude of vibrations varied from 6 50Hz and 0.44mm-6mm, respectively. The theoretical peak acceleration of the signals,
 calculated by [Amplitude × (2×π×frequency)²], ranged from 0.4g to 20.1g, where g denotes the
 unit of Earth's gravity (9.81m/s²). One trials investigated the acute effect of whole-body
 vibration,³⁰ while eight trials examined the effects of long-term whole-body vibration training. ^{19,}
 ^{25-29, 31, 32}

7

8 Methodological quality

9 The PEDro score of selected studies could be obtained by searching PEDro database, which

10 ranged from 4 to 9. Overall, only one trial in stroke was considered to have excellent

11 methodological quality (PEDro score=9), 31 and four studies (one in spinocerebellar ataxia²⁸,

12 and three in stroke^{29, 30, 32}) were regarded as having good methodological quality (PEDro score=

13 6-8), and four studies (three in cerebral palsy,^{19, 25, 26} one in multiple sclerosis²⁸) were fair quality

- 14 trials (PEDro score=4).
- 15

16 The level of evidence of each study was rated by two researchers and the agreement was

17 excellent with kappa=0.886 (p<0.001).One stroke trial were level 1b (PEDro ≥ 6 and sample

18 size>50), ³¹ eight were level 2b (PEDro< 6 or sample size \leq 50).^{19, 25-30, 32}

19

20 *Quality of whole-body vibration reporting*

All the selected studies explicitly reported the specific vibration device and vibration frequency
used. Vibration amplitude and vibration type (i.e. synchronous, side-alternating, stochastic) was
unknown in one study.²⁵ Six studies clearly reported whether the patients were supervised during

1	whole-body vibration invention. ^{19, 26, 29-32} However, only one study calibrated the whole-body
2	vibration device and reported the validated peak acceleration. ³¹

3

4 *Muscle spasticity measurement tools*

Various measurement tools were used to assess muscle spasticity in different studies. The
clinical measurement tools included Modified Ashworth Scale, ^{19, 25-27, 29-32} Multiple Sclerosis
Spasticity Scale-88,²⁷ Inventory of Non-Ataxia Symptoms,²⁸ and Visual Analogue Scale for
measuring self-perceived level of spasticity.³⁰ Other assessment tools included H-reflex,³⁰ tendon
reflex testing³⁰ and Pendulum test.¹⁹ Five of the studies used only one measurement tool to
examine muscle spasticity,^{25, 26, 29, 31, 32} while four studies involved two or more muscle tone
measurement tools.^{19, 27, 28, 30}

12

13 *Comparison group*

14 Six studies involved a comparison group that performed the same exercises as the whole-body

vibration group but without the vibration stimuli^{19, 27, 30, 31} or with sham vibrations ^{28, 29}(i.e.,

16 comparison 1 as defined in the Methods section) so that the effects of the whole-body vibration

17 alone could be delineated. Three studies incorporated a control group that was involved in other

18 activities (e.g. routine treatment, strength training) (i.e., comparison 2). ^{25, 26, 32} This comparison

19 would determine whether the whole-body vibration training overall (whole-body vibration and

20 exercise components) was better than other interventions.

21

22 Acute effect of whole-body vibration on muscle spasticity

23 The results of each study are presented in table 5 (supplementary data online).

1 *Comparison 1.* Only one trial studied the acute effect of whole-body vibration on spasticity when compared with the same exercise training but without whole-body vibration.³⁰ Chan et al. 2 ³⁰ employed four measurement tools (i.e. Modified Acworth Scale, Visual Analogue Scale, H-3 4 reflex, Achilles tendon jerk) to measure the change of ankle spasticity in patients with chronic stroke after a single session and the results were inconsistent. The Modified Ashworth Scale and 5 6 Visual Analogue Scale score were significantly more reduced in the whole-body vibration group compared to the control group after whole-body vibration, but not the H-reflex response (H-7 reflex, H_{max}/M_{max}) and Achilles tendon reflex on the affected side.³⁰ Postural control and 8 functional mobility were also improved significantly more in the whole-body vibration group.³⁰ 9

10

11 Effects of multiple sessions of whole-body vibration on spasticity

Comparison 1. Five studies (one multiple sclerosis trial,²⁷ one cerebral palsy trial,¹⁹ two stroke 12 trials,^{29, 31} one spinocerebellar ataxia trial²⁸) involved a control group in which the participants 13 underwent the same exercise as whole-body vibration group but without vibration stimulus or 14 sham vibration (Table 5, supplementary data online). The results were mixed. In between-group 15 analysis, Schyns et al.²⁷ (multiple sclerosis trial) reported significantly more reduction of muscle 16 17 spasm (muscle spasm item of Multiple Sclerosis Spasticity Scale-88) after 4 weeks of treatment, but no significant results on Modified Ashworth Scale score were found. In patients with 18 cerebral palsy, Cheng et al.¹⁹ found significantly more reduction of quadriceps spasticity in the 19 20 whole-body vibration group than the control group (medium to large effect sizes) as measured by the Modified Ashworth Scale and Pendulum test after a 4-week intervention period, and the 21 effects lasted up to 3 days after the termination of the intervention. In the two stroke trials, only 22 Pang et al.³¹ reported some favorable effects on spasticity. The knee Modified Ashworth Scale 23

score in the affected leg was significantly reduced in whole-body vibration group but not in the
control group.³¹ However, no between-group analysis was done.³¹ Another stroke trial by
Brogardh et al.²⁹ reported no treatment effect of whole-body vibration on spasticity. Finally, no
significant effect on spasticity was detected after whole-body vibration in patients with
spinocerebellar ataxia.²⁸

6

Among those studies that reported favorable effects of whole-body vibration on reducing
spasticity, ^{19, 27, 31} only Cheng et al. found the changes in six-minute-walk distance and timed upand-go performance were significantly correlated with the improvement of the relax index
derived from the Pendulum test. ¹⁹ Otherwise, no other study showed significant between-group
differences in mobility functions after the treatment period.^{27, 31} In contrast, Kaut et al., which
produced negative results on muscle tone, reported significantly more improvement in postural
and gait stability in the whole-body vibration group than controls.²⁸

14

Comparison 2. Three studies (two cerebral palsy trials,^{25, 26} one stroke trial³²) compared the 15 effect of multiple sessions of whole-body vibration treatment with other treatment modalities. 16 Ahlborg et al.²⁵ found significant reduction in Modified Ashworth Scale score of knee extensors 17 on the stronger side after whole-body vibration treatment among children with cerebral palsy, but 18 comparison with the resistance training group was not performed. In another cerebral palsy trial, 19 Ibrahim et al.²⁶ found a significant reduction of Modified Ashworth Scale score on the weaker 20 side after whole-body vibration. However, as revealed by between-group analysis, whole-body 21 vibration did not lead to better outcomes in lower limb Modified Ashworth Scale scores than 22 conventional physical therapy.²⁶ Improvement of Gross Motor Function Measurement in domain 23

D (standing) and E (walking, running, and jumping) was found in the whole-body vibration
group but not the control group.^{25, 26} However, no between-group analysis of these outcomes was
presented. Finally, Tankisheva et al.³² did not find any improvement of Ashworth Scale score in
both the whole-body vibration group and control group (habitual activity) after 6 weeks of
whole-body vibration among people with stroke.

6

7 *Side effects*

A total of 150 people with central nervous system disorders were exposed to whole-body 8 9 vibration in the nine selected studies. Eight studies actually reported whether there were any adverse events or not.^{19, 25-29, 31, 32} Among these, three studies explicitly stated that no adverse 10 events occurred.²⁶⁻²⁸ Brogardh et al.²⁹ reported that 15 out of 31 participants had transient mild 11 12 muscle soreness or muscle fatigue, but did not specify the number of these cases in each of the whole-body vibration and sham treatment groups. Tankisheva et al.³² reported that "some of the 13 participants described some itching in the legs after the first vibration sessions but this 14 phenomenon resolved spontaneously". Isolated cases of dizziness (n=3),³¹ muscle stiffness 15 (n=2),^{19, 25} back muscle soreness $(n=1)^{19}$ and lower limb soreness $(n=2)^{31}$ were also reported in 16 other studies. It is not clear whether any adverse effect occurred in Chan et al.³⁰ 17

18

19 Discussion

This is the first systematic review to examine the effects of whole-body vibration on spasticity among people with central nervous system disorders. The results showed that whole-body vibration may be useful in reducing leg muscle spasticity in cerebral palsy, but the effect is

- uncertain in multiple sclerosis, stroke and spinocerebellar ataxia. No clear association was found
 between the reduction in muscle spasticity and changes in functional measures.
- 3

4 Effect of whole-body vibration on muscle spasticity

The evidence related to the acute effect on spasticity of people with chronic stroke was provided 5 by one level 2b study only.³⁰ Although favorable results were shown with Modified Ashworth 6 Scale and Visual Analogue Scale, they were not accompanied by any significant between-group 7 differences in results generated from neurological assessment (H-reflex and tendon reflex 8 testing).³⁰ It should be noted that Visual Analogue Scale is a subjective measure of perceived 9 level of spasticity. The change in Visual Analogue Scale may be explained by placebo effect of 10 the whole-body vibration, as sham vibrations were not used.²³ The Modified Ashworth Scale, on 11 the other hand, is a single-item assessment tool that is ordinal in nature. However, parametric 12 rather than non-parametric statistics were used by the authors to analyze the data, which leads to 13 questions about the validity of the results.³⁰ Therefore, no solid conclusion can be made on the 14 acute effect of whole-body vibration alone on spasticity in people with stroke. It was suggested 15 in quasi-experimental studies that whole-body vibration would significantly inhibit H-reflex in 16 healthy populations³⁻⁶ and people with spinal cord injury.³³ The vibration intensity used in the 17 these studies was higher (frequency in 20~40 Hz and peak-to-peak amplitude 1~4mm) than that 18 adopted in Chan et al.³⁰ Therefore, apart from difference in subject characteristics, the difference 19 20 in whole-body vibration intensity may also explain the discordance of the results related to the acute effect on H-reflex. 21

1	Is there any evidence that whole-body vibration can effectively reduce spasticity after training of
2	longer durations (e.g., in the order of weeks)? All three cerebral palsy trials ^{19, 25, 26} reported
3	results in favor of whole-body vibration training but they provided level 2b evidence only.
4	Cheng et al. ¹⁹ demonstrated that adding whole-body vibration to exercise induced a significant
5	treatment effect on reducing quadriceps spasticity than exercise alone without whole-body
6	vibration. The other two cerebral palsy trials also found significant reduction in quadriceps
7	spasticity within the whole-body vibration group, but the comparison with the control group
8	(resistance training, conventional physical therapy) was either not done or not statistically
9	significant. ^{25, 26} Given the study design, it was impossible to delineate the effects of the vibratory
10	stimuli alone in these two studies. ^{25, 26} In addition, even if the imposed vibrations, rather than
11	the exercises done while receiving vibrations, are the main cause of the observed reduction in
12	spasticity, the findings of these two studies provided no evidence that whole-body vibration
13	training is better than other treatments in reducing spasticity in individuals with cerebral palsy.
14	Taken together, while all three cerebral palsy trials reported some positive effects on whole-body
15	vibration training on reducing spasticity with medium to large effect sizes, ^{19, 25, 26} the overall
16	evidence is not strong, considering the limitations of the study design of the latter two studies. ^{25,}
17	26

18

The evidence found in the stroke population is inconsistent. Of the three stroke trials, only Pang et al.³¹(level 1b) found significant reduction in spasticity within the whole-body vibration group. Upon examining the difference in subject characteristics and treatment protocols among these studies, no specific trends were identified that may explain the difference in results, except that the intervention period was longer in Pang et al.³¹(8 weeks) than the other two studies (6

weeks).^{29, 32} Overall, there is no strong evidence that the added whole-body vibration can confer
 additional effects on reducing spasticity post-stroke.

3

Similar to stroke, there is not sufficient evidence to support or refute the use of whole-body
vibration in reducing spasticity in individuals with multiple sclerosis (one level 2b study)²⁷ and
spinocerebellar ataxia (one level 2b study),²⁸ due to the limited number of studies.

7

When considering the overall evidence related to the effects of whole-body vibration on muscle 8 spasticity, only one cerebral palsy trial, ¹⁹ one stroke trial³⁰ and one multiple sclerosis trial²⁷ 9 reported some results that clearly point to beneficial effects of the imposed vibratory stimulation 10 alone. The protocols used in these three studies were very different. ^{19, 27, 30} In the cerebral 11 palsy¹⁹ and multiple sclerosis trials,²⁸ the vibration intensities used were greater (2.3g-20.1g Vs 12 1.6-2.3g), but the duration of the vibration exposure per session (3-10 minutes Vs 15 minutes) 13 was shorter when compared with the stroke trial.³⁰ Due to the small number of studies that 14 reported significant results, and the vast differences in the intervention protocols, we could not 15 determine the specific parameters that may account for the positive treatment outcomes. 16 17

18 *Relationship to functional level*

There is no consistent evidence to show that improvement in spasticity is correlated with improvement in functional ability of the study participants. In Chan et al.³⁰ (stroke trial), although the improvement in spasticity was accompanied by improvement in balance and mobility function, it is difficult to determine whether it was related to modification of post-stroke spasticity after whole-body vibration, as correlation analysis was not performed. Only Cheng et al.¹⁹ specifically reported that the change in timed up-and-go score was significantly associated
with the change in the relax index (Pendulum test) in children with cerebral palsy. Overall, the
evidence pertaining to the relationship between changes in muscle tone and those in functional
ability after whole-body vibration treatment is weak.

5

6 *Quality of reviewed articles*

Only one of the nine reviewed studies provided level 1b evidence.³¹ Four of nine studies had
very small sample size (<20),^{19, 25, 27, 32} which lowered the statistical power and limited the
generalizability of the results to the wider patient populations.

10

11 With few exceptions, the protocols of whole-body vibration were not described in adequate details, particularly the use of footwear and supportive device. Only one trial has calibrated and 12 validated the whole-body vibration dosage delivered to the patients (i.e. amplitude and 13 frequency).³¹ However, a recent study has shown that for most whole-body vibration platforms, 14 the actual frequency and amplitude of vibrations delivered are different from the intended 15 values.³⁴ The body weight of subjects would often influence the vibration intensity generation.³⁴ 16 Future studies should thoroughly describe the protocols in detail in accordance with the 17 guidelines set by the International Society of Musculoskeletal and Neuronal Interactions²¹ and 18 validate the vibration signals of platform before conducting the study. 19

20

Finally, the Modified Ashworth Scale was extensively used in the reviewed studies, despite its
low reliability, validity, and responsiveness.^{35, 36} Future research should use measurement tools

with good psychometric properties to examine the effects of whole-body vibration on muscle
 spasticity.

3

4 *Limitations at the review level*

Some potentially relevant studies may have been missed because reports not written in English
were excluded. Those articles that did not use appropriate words in the titles or abstracts may
also have been missed.

8

9 We used spasticity only as the outcome of interest. Other outcome measures were considered
10 only if spasticity was measured in the same studies, so as to examine whether changes in
11 spasticity were related to changes in functional performance. This review, therefore, was not
12 designed to assess whether whole-body vibration has therapeutic value on improving outcomes
13 other than spasticity (e.g., gait, balance, quality of life, etc.).

14

As the intervention protocols used differed on more than one whole-body vibration parameter (whole-body vibration type, frequency, amplitude, treatment duration and frequency), it is difficult to make meaningful comparisons across studies and delineate the independent effects of different whole-body vibration parameters. Meta-analysis was not possible due to the heterogeneity of the studies.

20

21 In conclusion, based on extensive review of the literature, there is some evidence that whole-

body vibration may be useful in reducing leg muscle spasticity in patients with cerebral palsy but

the evidence is of level 2b only. More high quality trials should be conducted to verify the results.

There is insufficient evidence to support or refute the notion that whole-body vibration alone
confers any significant effects on spasticity in stroke, multiple sclerosis and spinocerebellar
ataxia or that whole-body vibration is better than other alternative physical therapy or exercise
training in modifying spasticity in these patient populations. There is little evidence that wholebody vibration induced change in spasticity is related to change in functional performance
among people with central nervous system disorders.

7

8 Clinical message

• Whole-body vibration may be useful in reducing leg muscle spasticity in cerebral palsy.

The use of whole-body vibration on reducing muscle spasticity in multiple sclerosis was
 supported by one level 2b study only.

12 • There is insufficient evidence to support or refute the use of whole-body vibration on

13 reducing muscle spasticity in stroke or spinocerebellar ataxia.
