12   **Abstract**

13   A systematic field measurement was conducted at an island site (Wanshan Island, WSI) over

14   South China Sea (SCS) in autumn 2013. It was observed that mixing ratios of O$_3$ and its

15   precursors (such as volatile organic compounds (VOCs), nitrogen oxides (NO$_x$=NO+NO$_2$) and

16   carbon monoxide (CO)) showed significant differences on non-episode days and episode days.

17   Additional knowledge was gained when a photochemical box model incorporating the Master

18   Chemical Mechanism (PBM-MCM) was applied to further investigate the

19   differences/similarities of O$_3$ photochemistry between non-episode and episode days, in terms

20   of O$_3$-precursor relationship, atmospheric photochemical reactivity and O$_3$ production. The

21   simulation results revealed that, from non-O$_3$ episode days to episode days, 1) O$_3$ production

22   changed from both VOC and NO$_x$-limited (transition regime) to VOC-limited; 2) OH radicals

23   increased and photochemical reaction cycling processes accelerated; and 3) both O$_3$ production

24   and destruction rates increased significantly, resulting in an elevated net O$_3$ production over

25   the SCS. The findings indicate the complexity of O$_3$ pollution over the SCS.

26   **Key words**: Ozone; VOCs; Photochemical box model; Photochemistry; South China Sea

27   **Capsule:** Elevation of maritime O_3 and its precursors was attributable to the transport of

28   polluted continental air, implying impact of human activities on atmospheric composition

29   above the SCS.

1 Introduction

31   Tropospheric ozone (O_3), a major constituent of photochemical smog, is of great impact on

32   atmospheric chemistry, human health and climate change (NRC, 1991; NARSTO, 2000;

33   Seinfeld and Pandis, 2006). Ozone pollution is a complex phenomenon since it involves

34   precursor emissions, photochemical formation and dynamic transport on different scales (Jacob,

35   1999; Guo *et al.*, 2017). With the rapid urbanization and industrialization, the Pearl River Delta

36   (PRD) region has been experiencing severe O_3 pollution over the past decades (Chan *et al.*,

37   1998a, b; Ding *et al.*, 2004; Zhang *et al.*, 2007). The maximum hourly O_3 mixing ratio

38   frequently exceeds national air quality standard (100 ppbv), mainly attributed to the elevated

39   emissions of local precursors and regional/super-regional transport of O_3 and its precursors

40   from other parts of China (Wang *et al.*, 2003; Guo *et al.*, 2009, 2013). Previous studies found

41   that O_3 precursors such as volatile organic compounds (VOCs) and nitrogen oxides

42   (NO_x=NO+NO_2) emitted in urban areas can travel to the downwind rural areas or oceanic areas,

43   enhancing the photochemical O_3 formation in these areas (Finlayson-Pitts and Pitts, 1993;

44   Solberg *et al.*, 2004). Ozone photochemistry in the PRD region has been documented, including

45   VOC speciation and abundance (Lee *et al.*, 2002; Guo *et al.*, 2006, 2007, 2011; Liu *et al.*, 2008;

46   Ou *et al.*, 2015), in-situ photochemical O_3 production (Zhang *et al.*, 2007; Lyu *et al.*, 2016a;

47   Wang *et al.*, 2017a), process analysis of regional O_3 formation (Wang *et al.*, 2003; Zhang *et

48   al.*, 2008; Guo *et al.*, 2009; Wang *et al.*, 2010; Jiang *et al.*, 2010; Cheng *et al.*, 2010a),

49   atmospheric oxidative capacity (Xue *et al.*, 2016; Wang *et al.*, 2017b) and radical chemistry

50   (Lou *et al.*, 2010; Lu *et al.*, 2012, 2014; Ling *et al.*, 2014; Lyu *et al.*, 2016b), while limited

51   studies on O_3 formation were undertaken over the South China Sea (SCS, Wang *et al.*, 2005,

52   Ou Yang *et al.,* 2013). Since interaction between continental and maritime air sometimes forms

53   weak circulation cells in which pollutants become entrained, resulting in increased

54   concentrations, it is essential to investigate the chemical characteristics of O_3 formation over

55   the SCS.

56   Although the coastline of mainland China covers approximately 14,500 km, studies of the

57   characteristics of O_3 pollution in coastal areas are limited. Han *et al.* (2015) reported the

58   variation of surface O_3 over the East China Sea (ECS) and found that Chinese outflows brought

59   higher O_3 concentrations to the ECS. Ou Yang *et al.* (2013) investigated regional background

60   O_3 level at Dongsha Island, which is located between Taiwan and the Philippines in the

61   northern SCS. They revealed that during winter Asian monsoon, polluted air masses were

62   delivered from the northern continent to Dongsha Island by strong northeastern winds, resulting

63   in O_3 mixing ratios of ca. 60 ppbv. With the O_3 transport from the continent, O_3 precursors can

64   also be transferred to the maritime atmosphere and contribute to photochemical O_3 production.

65   However, limited studies have been carried out to improve our knowledge of photochemical

66   O_3 formation above the ocean. One of the reasons was the lack of comprehensive precursor

67   emissions data, especially VOC data, which hinders the investigation of mechanism of O_3

68   production in maritime environments. Although Wang *et al.* (2005) reported comprehensive

69   observations of O_3 and its precursors at Tai O, a coastal site in Hong Kong, and established

70   seasonal profiles of background air pollutants over the SCS and regional pollution of PRD, the

71   photochemical O_3 formation in the region was not fully elaborated.

72   To fill the gap, continuous measurements of air pollutants, including O_3 and its precursors,

73   were conducted at a remote island site (Wanshan Island, WSI) in the SCS from August to

74   November 2013. A photochemical box model incorporating the Master Chemical Mechanism

75   (v3.2) was applied to simulate the photochemical processes of local O_3 production. The

76   scientific objectives of this study are (1) to investigate the causes of high O_3 episodes over the

77   SCS; (2) to understand the regime and O_3 production conditions over the SCS in order to inform

78   policy decisions; and (3) to explore the impact of VOCs on O_3 formation pathways over the

79   SCS.

80   **2 Methodolgy**

81   2.1 Sampling site

82   Real-time field measurements of trace gases were carried out at the WSI site in the SCS (Figure

83   S1). The WSI site (21.93° N, 113.73° E) is about 34 km south from the coast, and is bounded

84   to the north by the Pearl River Estuary. The distance from WSI to the urban center of Hong

85   Kong, Macau and Zhuhai is about 64 km, 35 km and 40 km, respectively. The island has an

86   area of 8.1 km^2 and a population of about 3000. The island has a subtropical maritime climate

87   and is a downwind location of the PRD region in autumn and winter, when the Asian winter

88   monsoon dominates. The measurement facilities were established on the rooftop of the

89   National Marine Environmental Monitoring Station on Wanshan Island with a height of about

90   65 m above sea level and ~10 m above ground level.

91   2.2 Measurement methods

92   2.2.1 On-line measurements of O_3, CO, SO_2 and NO_x

93   Sampling equipment was installed in an air-conditioned room at the top floor of the National

94   Marine Environmental Monitoring Station. A 5 m long perfluoroalkoxy (PFA) Teflon tube,

95   with inner diameter of 9.6 mm and outer diameter of 12.7 mm, was used as a sampling tube.

96   The inlet of the sampling tube was 2 m above the rooftop of the building, while the other end

97   was coupled to a PFA manifold which linked together all the gas analyzers in the room. A

98   bypass pump connected to the manifold drew ambient air at a rate of 5 L min^{-1} into the intakes

99   of the gas analyzers.

100 Trace gases including O_3, NO_x, CO and SO_2 were simultaneously monitored during the

101 sampling period (11 August – 22 November, 2013). Briefly, the target pollutants were

102 measured with commercial analyzers developed by Advanced Pollution Instrumentation (API)

103 Inc. A UV photometric analyzer (API model 400E with a detection limit of 0.6 ppbv) was used

104 to monitor O_3, while $NO-NO_2-NO_x$ was measured with a chemiluminescence analyzer (API

105 model 200E with a lower detectable limit of 0.4 ppbv) equipped with a replaceable

106 molybdenum-converter cartridge. A gas filter correlation trace level CO analyzer (API model

107 300EU with a detection limit of 0.02 ppmv) with a heated, platinum CO scrubber to correct

108 its baseline was utilized to measure CO, and SO_2 was detected with a pulsed UV fluorescence

109 monitor (API model 100E with a detection limit of 0.4 ppbv). In addition, meteorological

110 parameters (solar radiation, temperature, relative humidity, wind speed and wind direction)

111 were continuously measured by a weather station (Vantage Pro 2, Davis Inc).

112 For quality control, a transfer standard (Thermo Environmental Instruments (TEI), 49PS) was

113 used to calibrate the O_3 analyzer. For CO, SO_2 and NO, NIST (National Institute of Standards

114 and Technology)-traceable standard (Scott-Marrin, Inc.) was diluted using a dynamic calibrator

115 (Environics, Inc., Model 6100). The standard contained 156.5 ppm CO (±2 %), 15.64 ppm SO_2

116 (±2 %), and 15.55 ppm NO (±2 %). Through injecting scrubbed ambient air (TEI, Model 111)

117 and a span gas mixture, these analyzers were calibrated. In addition, a data logger

118 (Environmental Systems Corporation, Model 8832) was used for calibration control and data

119 collection, with a time resolution of 1 min intervals (Guo *et al.*, 2013).

120 2.2.2 VOCs sampling and analysis

121 Intermittent whole-air canister samples for VOCs and carbonyl cartridge samples for

122 aldehyldes were obtained at WSI for 8 O_3 episode days and 13 non-O_3 episode days. The O_3

123 episode days were defined as the days with maximum hourly average O_3 value exceeding 100

124 ppbv (China's Grade II Standard). Specifically, the 13 non-O_3 episode days included 11-12,

125   18, 26 September, 9-10, 17, and 30-31 October, and 18-21 November 2013, while the 8 O_3

126   episode days were 2-4 and 22-25 October, and 15 November 2013. The whole-air samples

127   were collected using evacuated 2-L electro-polished stainless steel canisters. The canisters

128   were cleaned, conditioned and evacuated before sampling. A flow-restrictor was used to collect

129   air samples over 1-hour integration. Seven 1-hr VOC samples (every two hours from 7:00 –

130   19:00 LT inclusive) were collected on each of the 13 non-O_3 episode days and the 8 O_3 episode

131   days at the site with additional samples collected at 01:00, 03:00, 05:00 and 21:00 on episode

132   days. The speciation and abundance of individual VOCs in the canisters were determined by

133   gas chromatography (GC) with flame ionization detection (FID), and GC with electron capture

134   detection (ECD) and mass spectrometer detection (MSD). 59 C_2-C_{11} hydrocarbon species were

135   quantified. The detection limits of VOCs ranged from 3 to 57 pptv with a measurement precision

136   of 2-5%, and a measurement accuracy of 5%. Detailed descriptions of the analysis system,

137   quality control and quality assurance for VOC samples are provided elsewhere (Simpson *et al.*,

138   2010; Zhang *et al.*, 2012).

139   Furthermore, 2h carbonyl cartridge samples were simultaneously collected every two hours

140   during 07:00-19:00 using acidified 2,4-dinitrophenylhydrazine (DNPH) silica cartridges at a

141   flow rate of 0.4-0.6 L min^{-1}. The procedures including the pretreatment, the configuration of

142   the analysis system, and the methods of the quality control and quality assurance for carbonyl

143   samples can be found in detail elsewhere (Guo *et al.*, 2009). Briefly, the carbonyl samples were

144   analyzed using high performance liquid chromatography (HPLC) with an auto-sampler. The

145   identification and quantification were on the basis of retention times and peak areas of the

146   corresponding calibration standards. Five standard concentrations, covering the concentrations

147   of interest for ambient air, were selected to calibrate the instrument. Typically, 11 C_1–C_9

148   carbonyl compounds were quantified with a detection limit of ~0.2 ppbv and a measurement

149   precision of ~10%.

2.3 Photochemical box model (PBM)

2.3.1 General description

In this study, the photochemical formation of O_3, free radicals and intermediate products at WSI on 8 O_3 episode days and 13 O_3 non-episode days were simulated using a photochemical box model incorporating the Master Chemical Mechanism (PBM-MCM). The MCM adopts a near-explicit mechanism, involving 5,900 chemical species and around 16,500 reactions including the reaction between radicals (*i.e.*, OH) and SO_2 (Long *et al.*, 2017). Since methane and tropospheric molecular hydrogen account for a significant fraction of the OH to HO_2 conversion in the background atmosphere, their roles in the model are considered and their values are set to be 1.95 ppmv and 0.5 ppmv, respectively, according to our past observations (Ling *et al.*, 2014; Lyu *et al.*, 2015a). Previous studies show that it performs well in calculating the O_3 production (Jenkin *et. al.*, 1997, 2003; Saunders *et. al.*, 2003).

Different from the photochemical trajectory model (PTM) with MCM which is based on emission inventories (Cheng *et al*., 2010a; Derwent, 2017), in this study the observed values of air pollutants (O_3, NO_x, CO, SO_2 and 51 VOCs, see Table S1) and meteorological parameters (temperature and relative humidity) between 0700 and 1900 were used to constrain the model (Guo *et al*., 2013; Ling *et al*., 2014; Lyu *et al*., 2015a, b). It is noteworthy that since trace gases and metrological parameters were measured in minute intervals, they were averaged to hourly values prior to model input. One of the purposes is to minimize the influence of variations within an hour as the levels of reactive pollutants would vary from their initial hourly values by the end of each hour due to radical oxidation. Because the VOCs and OVOCs were measured at 2-hourly intervals, a method based on the mass conservation of a species inside a fixed Eulerian box was utilized to obtain hourly VOC and OVOC profiles from the limited samples (Zhang *et al.*, 2007; Lyu *et al.*, 2016a). In addition, model sensitivity tests on the

174   measurement uncertainties of NO_x and VOCs showed negligible impact on the simulated O_3

175   production (Figures S2 and S3).

176   Apart from the chemical reactions, the model considered other modules such as photolysis rate,

177   dry deposition and the boundary layer height. The photolysis rates of different chemicals in the

178   model were parameterized using the photon flux determined from the Tropospheric Ultraviolet

179   and Visible Radiation (TUVv5) model (Lam *et al.*, 2013), while the dry deposition module

180   included the dry deposition of air pollutants, which were parameterized as an average

181   deposition rate within the mixed layer height (MLH). The MLH was assumed to vary from 300

182   m at night to 1400 m during the daytime (Lam *et al.*, 2013). Sensitivity runs with MLHs of 900

183   m and 1900 m (1400 ± 500 m) indicated that its impact on O_3 simulation was minor (<3%)

184   (Figure S4). It should be noted that the PBM-MCM model did not consider physical processes,

185   *i.e.*, vertical and horizontal transport.

186   Facsimile software (Curtis and Sweetenham, 1987) was used to integrate the model system of

187   differential equations with integration output set each hour. The model output included the

188   simulated mixing ratios of O_3, radicals and intermediates. More detailed descriptions of the

189   PBM-MCM are provided in Ling *et al.* (2014), Guo *et al.* (2013) and Cheng *et al.* (2010a).

190   2.3.2 Photolysis rates in the model

191   Since direct measurements of $j(O^1D)$ and $j(NO_2)$ were not obtained during this sampling

192   campaign, the measured total solar radiation was applied to calibrate the photolysis frequencies

193   by comparing with the simulation results of the TUVv5 model

194   (http://cprm.acom.ucar.edu/Models/TUV/Interactive_TUV/). In the online TUVv5 model, the

195   surface albedo of 0.1 and the overhead O_3 column density of 323 Dobson units were applied.

196   The calculated solar radiation was obtained by regulating the parameter of optical depth to get

197   close to the measurements, while the photolysis frequencies were provided by the online TUV

198   model using the same physical parameters. Then, the PBM-MCM model used the calibrated

199   TUV photolysis frequencies to simulate the photochemical reactions.

200   2.3.3 Model performance

201   The index of agreement (IOA), which indicates the matching degree between the simulated

202   and observed O_3 (Equation 1), was used to evaluate the model performance (Huang *et al.*, 2005;

203   Lyu *et al.*, 2015a; Wang *et al.*, 2015).

204    $$\text{IOA} = 1 - \frac{\sum_{i=1}^{n}(O_i - S_i)^2}{\sum_{i=1}^{n}(|O_i - \bar{o}| + |S_i - \bar{o}|)^2}$$ (Eq. 1)

205   where S_i and O_i are simulated and observed hourly values, respectively, $\bar{o}$ represents the

206   average observed values, and *n* is the sample number. The range of IOA is 0~1. The higher the

207   IOA value is, the better agreement between simulated and observed values is (Huang *et al.*,

208   2005).

209   2.3.4 Estimate of relative incremental reactivity (RIR)

210   The sensitivity of O_3 formation to precursors was assessed using the relative incremental

211   reactivity (RIR), which was calculated from the output parameters of the PBM-MCM

212   (Cardelino and Chameides, 1995). RIR reflects the relative variation in O_3 production rate for

213   a change of mixing ratios in precursors. A larger positive RIR of a given precursor indicates a

214   higher probability that O_3 production will be more significantly reduced by cutting down

215   emissions of this precursor. The calculation of RIR values refers to the following equation:

216    $$\text{RIR}(X) = \frac{[P_{O_3\text{-}NO}^{S}(X) - P_{O_3\text{-}NO}^{S}(X - \Delta X)]/P_{O_3\text{-}NO}^{S}(X)}{\dfrac{\Delta S(X)}{S(X)}}$$ (Eq. 2)

217   X is a specific precursor (*i.e.*, VOCs, NO_x, or CO); S(X) is the observed mixing ratio of

218   precursor X (ppbv); $\Delta S(X)$ is the hypothetical change of mixing ratio of X; $P_{O_3-NO}^{S}(X)$ is the

219 net O_3 production in a base run with original mixing ratios, while $P^S_{O_3-NO}(X - \Delta X)$ is the net

220 O_3 production in a second run with a hypothetical change $(\Delta S(X))$ (10% in this study). Ozone

221 titration by NO was considered in both runs. The O_3 production $P^S_{O_3-NO}$ was calculated

222 according to Eq. 3 - Eq. 5. The superscript "S" represents the specific sampling site, which is

223 WSI site in this study. Detailed calculation method is provided in Ling *et al.* (2014).

224 2.3.5 Simulation of photochemical pathways and radicals

225 The net O_3 production (P_{O3-NO}) was the difference between O_3 gross production (G_{O3-NO}) and

226 O_3 destruction (D_{O3-NO}) (Equation 3). G_{O3-NO} was calculated by the oxidation of NO by HO_2

227 and RO_2 (Equation 4), while D_{O3-NO} was calculated by O_3 photolysis and reactions of O_3 with

228 OH and HO_2 (Equation 5). Among Equations 3-5, O^3P, O^1D, NO and NO_2 were put into

229 instantaneous steady state. All radicals and intermediates were obtained from the outputs of the

230 PBM-MCM. The constants (k) represent the rate coefficients of corresponding reactions,

231 respectively. The superscript '*i*' in equation 4 refers to individual RO_2.

$$P_{O_3-NO} = G_{O_3-NO} - D_{O_3-NO} \qquad \text{(Eq. 3)}$$

$$G_{O_3-NO} = k_{HO_2+NO}[HO_2][NO] + \sum k_{RO_2i+NO}[RO_i][NO] \qquad \text{(Eq. 4)}$$

$$D_{O_3-NO} = k_{HO_2+O_3}[HO_2][O_3] + k_{OH+O_3}[OH][O_3] + k_{o(^1D)+H_2O}[O(^1D)][H_2O] + \qquad \text{(Eq. 5)}$$
$$k_{OH+NO_2}[OH][NO_2] + k_{alkenes+O_3}[alkenes][O_3]$$

232 **3 Results and discussion**

233 3.1 General features

234 An overview of this sampling campaign from August to November was given by Wang *et al.*

235 (2017b). In this study, we mainly focused on the 8 O_3 episode days and 13 non-O_3 episode days

236 at WSI when trace gases, VOCs and OVOCs were all monitored. Table 1 presents the statistical

237 description of O_3, CO, SO_2, NO, NO_2 and TVOCs during the 8 O_3 episode days and 13 non-

238   O_3 episode days at WSI. The TVOCs was defined as the sum of 70 measured VOC species

239   (Table S1). It was found that both O_3 and its precursors had higher mixing ratios on O_3 episode

240   days than on non-O_3 episode days ($p<0.05$), partly due to different meteorological conditions

241   during the two periods. Figure S5 displays the mean wind fields on O_3 episode and non-O_3

242   episode days at WSI. North winds dominated during episodes, which transported dirty

243   continental air masses to the maritime site, leading to elevated levels of air pollutants. In

244   contrast, the winds turned to be eastern direction on non-O_3 episode days, which brought less

245   polluted maritime/coastal air to the site, resulting in low mixing ratios of air pollutants.

246   Moreover, since O_3 photochemistry is closely associated with the speciation and abundance of

247   its precursors, the different levels and compositions of O_3 precursors may alter the

248   photochemical pathways and subsequently the O_3-precursor relationships and O_3 production

249   between O_3 episode and non-O_3 episode days in the maritime atmosphere. As such, the O_3

250   photochemistry on O_3 episode and non-O_3 episode days over the SCS was elaborated using the

251   PBM-MCM model below.

252   **Table 1**. Statistical description of air pollutants on O_3 episode and non-O_3 episode days at WSI
253   (unit: ppbv; S.D.: standard deviation)

	Episode		Non-episode	
	Average ± S.D.	Maximum	Average ± S.D.	Maximum
O_3	74.1±34.2	152.3	53.6±15.1	81.5
CO	410±80	640	210±10	420
NO	0.6±1.0	5.5	0.4±0.9	8.5
NO_2	7.1±5.3	28.5	1.9±3.1	17.5
SO_2	4.4±1.9	8.8	2.1±1.0	6.4
TVOCs	26.3±9.8	74.8	15.5±7.1	39.3

254

255   3.2 Model verification

256   Prior to the study of local O_3 formation mechanisms, the PBM-MCM model performance was

257   evaluated. Figure 1 compares day-to-day patterns of simulated and observed O_3 on the 21 days.

258   It was clear that the model well simulated the O_3 variations, which started to increase in the

259   morning, reached peak value in the afternoon, and then decreased to low values in the evening.

260   The discrepancy of daily extremes (*i.e.*, maximums and minimums) between the simulated and

261   observed values was ±20%. The simulated values were generally lower than the observations

262   and the IOA of the 21-day simulation was 0.73, in line with the IOA values for the O_3

263   simulations of other models (0.68 – 0.89) (Wang *et al.*, 2015; Lyu *et al.*, 2015a, b, 2016a, b;

264   Wang *et al.*, 2017a), suggesting that the model performance on O_3 simulation in this study was

265   acceptable.

266   The difference between the observations and simulation results was partly because the physical

267   processes in the atmosphere, such as horizontal and vertical transport, were not considered in

268   the PBM-MCM. The speculation is reasonable because the PBM-MCM was mainly simulating

269   local O_3 production, while the vertical and horizontal transport was related to regional transport

270   which was demonstrated weaker on episode days than on non-episode days in the study region,

271   leading to lower model-observation agreement on non-episode days (Wang *et al.*, 2017b; Guo

272   *et al.*, 2013; Ding *et al.*, 2004). In addition, other factors such as uncertainty of measured

273   precursors, mixed layer height set-up in the model, and "spin-up" time might also influence the

274   model-observation agreements. For example, since the VOCs and OVOCs were intermittently

275   measured in this study, a "spin-up" time before the modeling days was not applied in the model

276   to get the radical intermediates steady which might have caused a slight underestimation of the

277   simulated O_3 production and its sensitivity to precursors (Wang *et al.*, 2017a).
Figure 1. Simulated and observed O$_3$ on the 21 sampling days at WSI.

3.3 O$_3$-precursor relationships

To understand the causes of O$_3$ formation at a given site, O$_3$-precursor relationships were first investigated. Figure 2 shows the average RIR values on non-O$_3$ episode and O$_3$ episode days at WSI. During non-O$_3$ episode days, the RIR values of all precursors were positive while NO$_x$ had the highest RIR value (0.64±0.05), and other precursors, *i.e.*, anthropogenic VOCs (AVOCs, 48 species for model input), biogenic VOCs (BVOCs, *i.e.*, isoprene and *α/β*-pinenes. See further classification in Table S1) and CO, all had values lower than 0.1, suggesting that O$_3$ production responded most sensitively to NO$_x$ and less to VOC and CO, implying a NO$_x$ limited regime. The result was consistent with previous studies that O$_3$ production was both NO$_x$ and VOC limited (transition regime) at a rural site of Guangzhou (Backgarden) in the inland PRD region (Lu *et al.*, 2010).

In comparison, on O$_3$ episode days AVOC had the highest RIR value (0.54±0.04) while the values of BVOC and CO were lower than 0.2, implying that the O$_3$ formation was sensitive to AVOC, *i.e.*, VOC limited. Moreover, the RIR value of NO$_x$ was negative (-0.17±0.02),

13

294   suggesting that cutting NO_x would increase the O_3 formation. The RIR patterns during episodes

295   were similar to previous results obtained at different urban sites in Hong Kong (Cheng *et al.*,

296   2010b; Ling *et al.*, 2013; Guo *et al.*, 2013) and in the inland PRD region (Zhang *et al.*, 2007;

297   Lu *et al.*, 2010).

298   In summary, the O_3-precursor relationships over the SCS suggest that controlling NO_x

299   emissions during non-episode days is more effective to O_3 reduction, while controlling VOC

300   emissions on episode days results in the mitigation of O_3 formation at the site. The different O_3

301   control regimes between non-O_3 episode and O_3 episode days reveal the variations of chemical

302   compositions during these two different events though the reasons warrant further investigation.
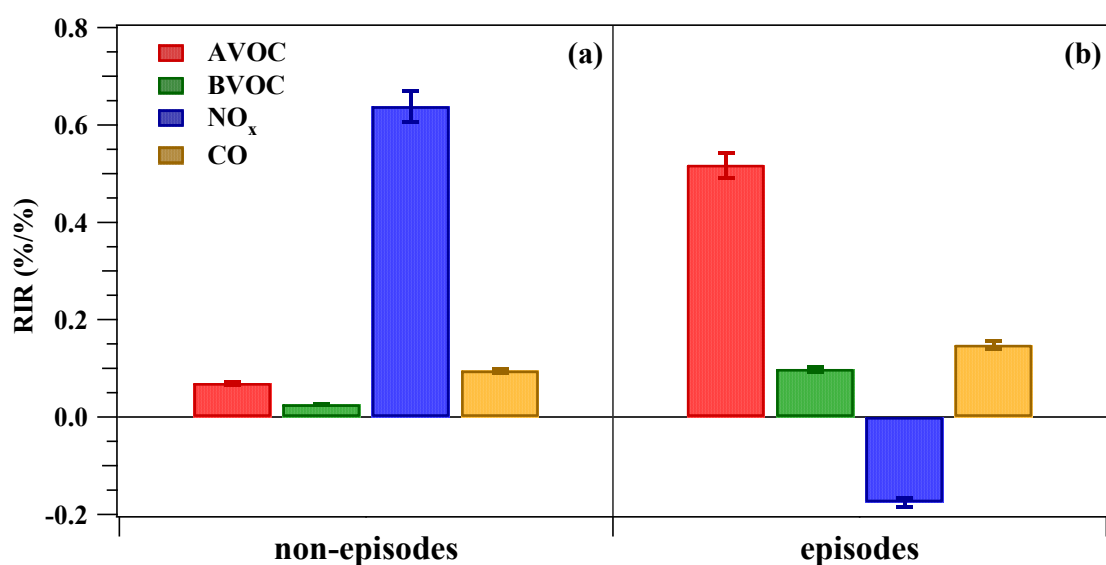

303

304   Figure 2. RIR values of O_3 precursors, *i.e.*, AVOC, BVOC, NO_x and CO at WSI on (a) O_3 non-

305   episode days and (b) O_3 episode days. Error bars are the 95% C. I. of the averages. Higher RIR

306   value of a precursor indicates that O_3 formation is more sensitive to it, whereas a negative RIR

307   value of a precursor implies that cutting it will increase the O_3 formation.

308   The sensitivity of O_3 formation to individual VOC species was further evaluated. Figure 3

309   presents the top 10 AVOC species (as determined by their RIR values) at WSI on non-O_3

310 episode days and O$_3$ episode days. It is noteworthy that isoprene was ranked No. 2 based on its

311 RIR value. However, since it is a BVOC, it is omitted in Figure 3. The results indicated that

312 though 51 VOC species were input into the PBM-MCM, the summed RIR values of top 10

313 AVOC species and isoprene occupied 77% and 13% of the overall RIR values at WSI,

314 respectively, reflecting that O$_3$ formation over the SCS was ascribed to a minority of VOC

315 species.

316 In comparison, all 10 AVOC species had much higher RIR values on O$_3$ episode days, implying

317 that controlling these VOC species would be more effective to limit O$_3$ formation on episode

318 days. Furthermore, the top 4 VOC species were the same on non-O$_3$ episode days as those

319 during episodes, indicating that control measures should always concentrate on these VOC

320 species to reduce O$_3$ pollution over the SCS. In addition, the RIR value of formaldehyde (an

321 oxygenated VOC (OVOC) species) was much higher than others on episode days, suggesting

322 important contribution of OVOC to O$_3$ formation in the maritime atmosphere.
323

324 Figure 3. Average RIR values of top 10 AVOC species at WSI on non-O$_3$ episode days (blue)

325 and episode days (red). The top 10 AVOC species are determined by their RIR values. Error

326 bars indicate the 95% C. I. of the averages.

327   3.4 O_3 photochemistry

328   3.4.1 Photochemical cycling

329   Ozone formation involves a series of complex reaction cycles of radicals (such as OH, HO_2,

330   and RO_2) in which CO and VOCs are continually oxidized. Briefly, OH radicals initially

331   oxidize the precursors (*i.e.*, VOCs, CO and NO_x) and result in O_3 formation. The cycling

332   between OH and HO_2 accelerates the chain-propagation reactions (see Text S1 in the

333   Supplementary for further description). Therefore, the concentrations and cycling of OH and

334   HO_2 are important parameters affecting O_3 photochemistry.

335   Figure 4 shows the average variations of simulated OH and HO_2 on non-O_3 episode and O_3

336   episode days at WSI. The maximum concentrations of OH and HO_2 were respectively 9.2×10^6

337   and 4.7×10^8 molecules cm^{-3} (equivalent to 0.37 and 19 pptv, respectively) on episode days, and

338   4.9×10^6 and 5×10^8 molecules cm^{-3} (0.2 and 20 pptv) on non-episode days, respectively. The

339   average OH mixing ratio during episodes ($4.2 \pm 1.1 \times 10^6$ molecules cm^{-3}) was about 70%

340   higher ($p<0.05$) than that during non-O_3 episodes ($2.5 \pm 0.8 \times 10^6$ molecules cm^{-3}), reflecting

341   higher photochemical reactivity on episode days. In contrast, the average HO_2 mixing ratio

342   during episodes ($2.2 \pm 0.9 \times 10^8$ molecules cm^{-3}) was comparable ($p>0.05$) to that during non-

343   O_3 episodes ($2.6 \pm 0.6 \times 10^8$ molecules cm^{-3}). The larger variations of OH and HO_2 levels

344   before 13:00 during episodes were likely due to larger variations of mixing ratios of NO_x in the

345   morning (see Figure S6), which affected radicals through the reactions of HO_2+NO, OH+NO

346   and OH+NO_2.

347

348
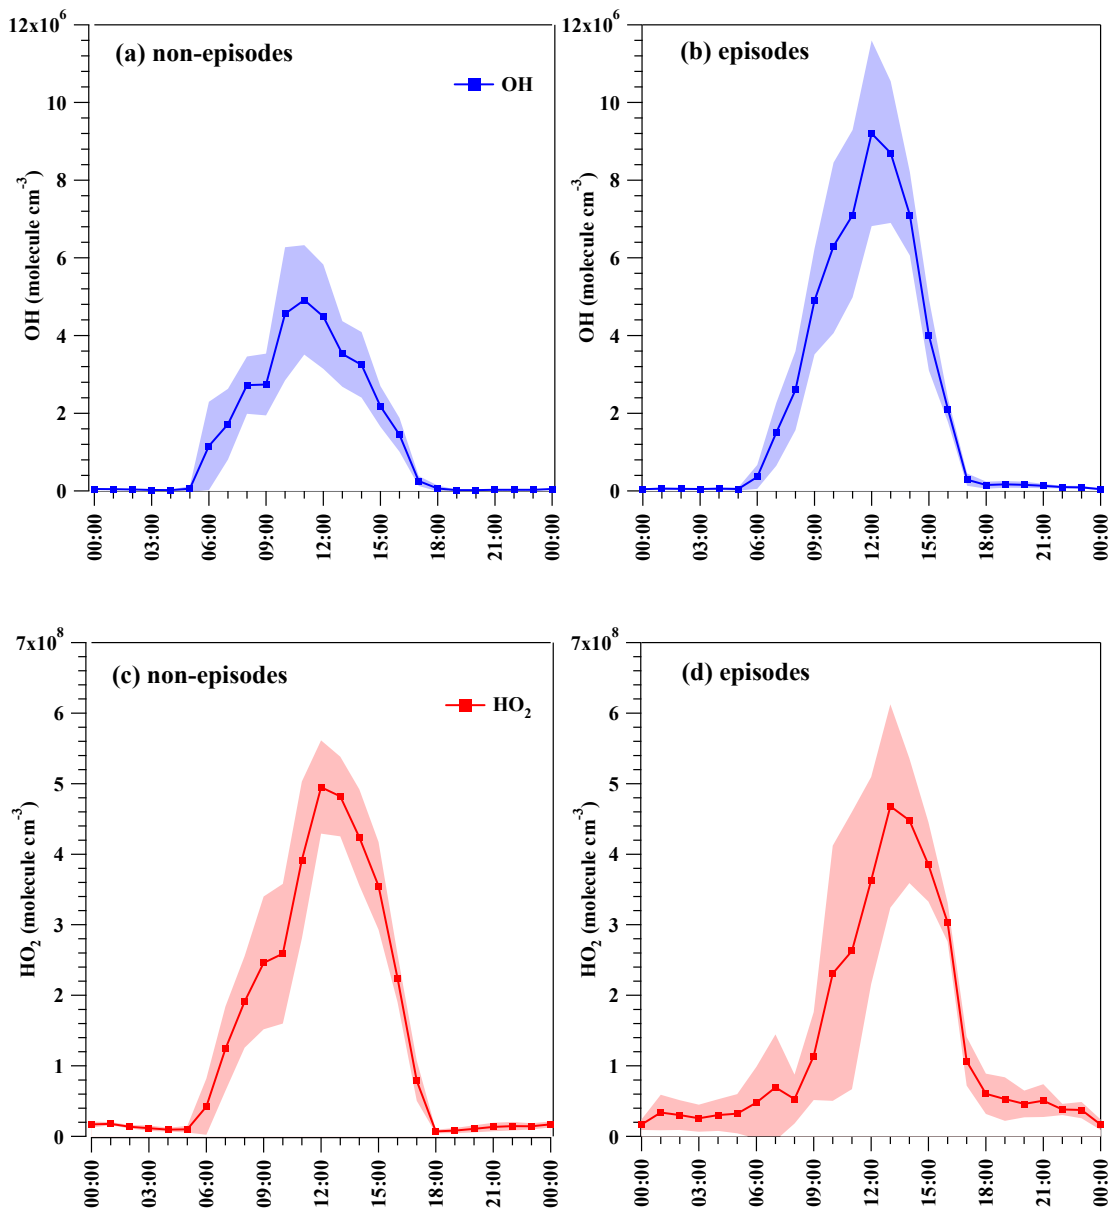

Figure 4. Simulated average temporal variations of OH on (a) non-O_3 episode days and (b) O_3 episode days, and HO_2 radicals on (c) non-O_3 episode days and (d) O_3 episode days at WSI. The shaded area indicates the 95% confidence interval of the data.

Figure 5 illustrates the predominant production and loss pathways of OH and HO_2 on non-O_3 episode days and episode days at WSI. In general, the overall formation or loss rates of OH

355   and HO_2 during episodes ($10.3\pm0.9\times10^7$ and $9.0\pm2.3\times10^7$ molecules cm^{-3} s^{-1}, respectively)

356   were much higher than those on non-episode days ($3.3\pm1.4\times10^7$ and $3.1\pm0.7\times10^7$ molecules

357   cm^{-3} s^{-1}, respectively) ($p<0.05$), suggesting more efficient radical cycling on episode days (see

358   Text S1 in the Supplementary for further description of radical cycling).

359   Specifically, during non-O_3 episodes, the reaction of HO_2+NO was the most predominant

360   pathway to generate OH, followed by O_3 photolysis, HONO photolysis and ozonolysis of

361   alkenes, with contributions of 75%, 18%, 5% and 2 %, respectively (Figure 5a). In contrast,

362   OH was mainly consumed by reactions with VOCs (68 %) and CO (23 %), while the reactions

363   of OH with NO_2 (7%) and NO (2 %) were negligible. For HO_2 formation, the reaction of

364   RO_2+NO (59%) and the reaction of OH with CO (26%) were the main sources, followed by

365   the reaction of OH with HCHO (9%), HCHO photolysis (5%), and ozonolysis of alkenes (1%)

366   (Figure 5c). Meanwhile, HO_2 was mainly consumed by reacting with NO (74%), followed by

367   the reaction between HO_2 and RO_2 (17%), and the reaction between HO_2 and HO_2 (9%).

368   In comparison, during episodes, the predominant reaction pathways for radical formation and

369   loss were the same as those on non-O_3 episodes, but the radical formation/loss rates for most

370   of the reaction pathways were higher. With the increase of the precursors (*i.e.*, VOC, CO and

371   NO_x; Table 1) and OH radicals (Figure 4) during episodes, the reaction pathways of OH with

372   NO, NO_2, CO and VOC significantly facilitated the OH loss (Figure 5b). The OH loss rates for

373   the pathways of VOC+OH and CO+OH increased ($p<0.05$) by about 1.2 and 2.4 times on

374   episodes, respectively, compared to those on non-O_3 episodes, which promoted the production

375   of peroxy radicals (*i.e.*, RO_2 and HO_2) to accelerate the propagation of the chain reactions.

376   Indeed, in the HO_2 formation pathways, the reaction rate of RO_2+NO doubled during episodes

377   (Figure 5d). Meanwhile, both photolysis of HCHO and reaction of HCHO+OH increased ~66%

378   and ~195% (Figure 5d), respectively, compared to non-O_3 episodes, which also accelerated the

18

379   HO2 formation on episode days. Consequently, the reaction rate of HO2+NO → OH+NO2 on

380   episodes became 3.6 times that on non-O3 episodes (shown in both the OH formation pathway

381   in Figure 5b and the HO2 loss pathway in Figure 5d). As the pathways of both RO2+NO and

382   HO2+NO out competed O3 from the null cycle of NO-NO2-O3, it is apparent that O3 formation

383   was strengthened from non-O3 episode days to episode days over the SCS.

384

385
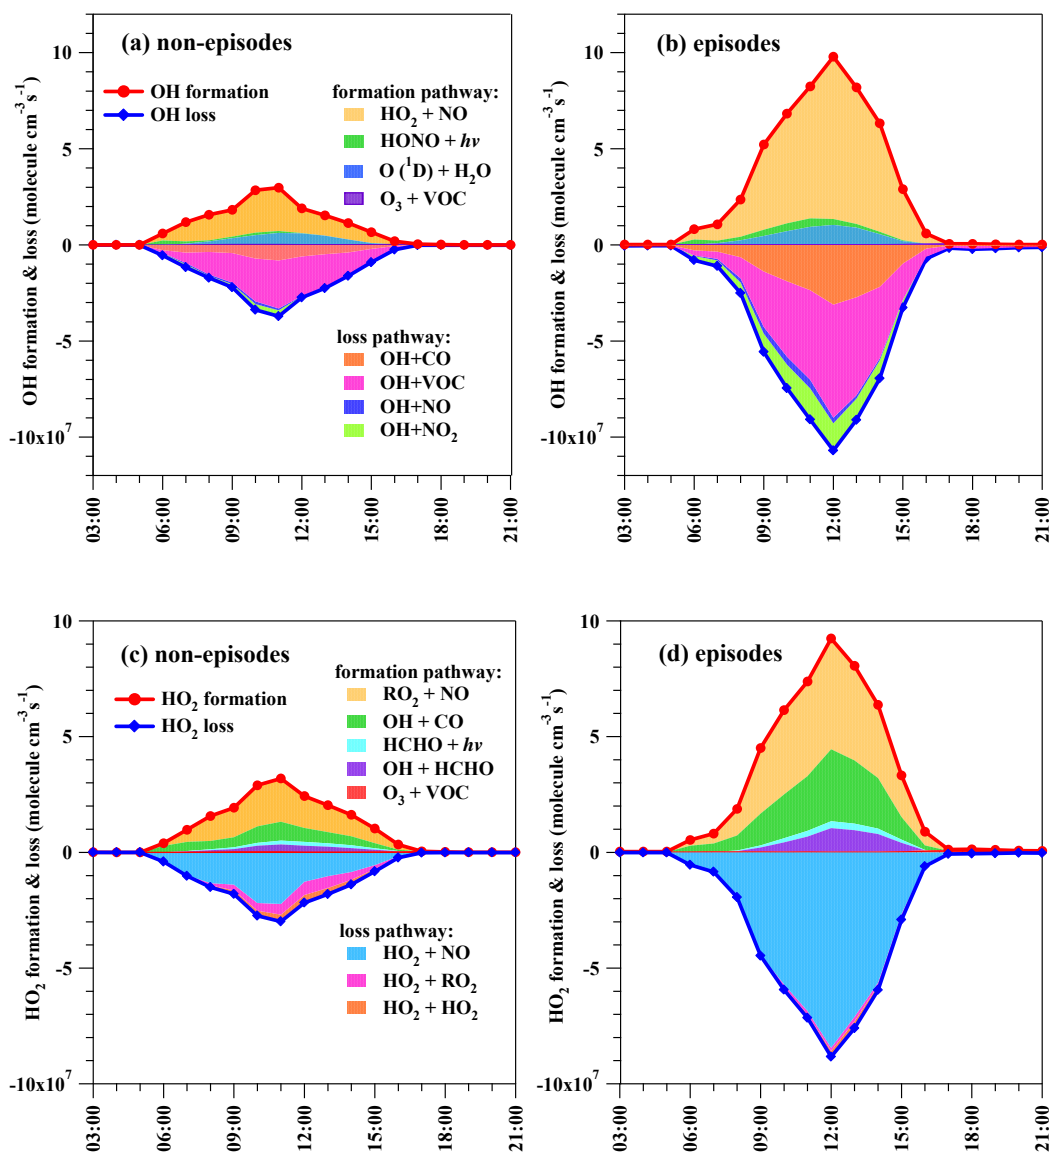

386   Figure 5. Simulated average formation and loss rates of OH on (a) non-O3 episodes and (b) O3

387   episodes, and HO2 on (c) non-O3 episodes and (d) O3 episodes at WSI.

388   3.4.2 In-situ net O_3 production

389   Figure 6 depicts the simulated diurnal profiles of O_3 production and destruction rates on

390   episodes and non-O_3 episodes at WSI. Overall, both O_3 production and destruction rates

391   increased on episodes, compared to those on non-O_3 episodes. Further, the O_3 production was

392   significantly greater than the O_3 destruction on both episode and non-O_3 episode days,

393   indicative of net O_3 production over the SCS. In addition, the daytime average net O_3

394   production rate on episode days (5.7 ± 1.1 ppbv h^{-1}) was much higher than that (1.8 ± 0.4 ppbv

395   h^{-1}) on non-O_3 episode days ($p < 0.05$).

396   The main pathways of O_3 production and destruction are also displayed in Figure 6. The O_3

397   production was dominated by the reaction of HO_2 with NO, with an average production rate of

398   4.7 ± 0.9 ppbv h^{-1} (relative contribution: 63%) and 1.3 ± 0.3 ppbv h^{-1} (53%) on episodes and non-

399   O_3 episodes, respectively, while the NO oxidation by RO_2 accounted for 2.8 ± 0.5 ppbv h^{-1} (37%)

400   and 1.1 ± 0.2 ppbv h^{-1} (47%), respectively. It is noteworthy that RO_2+NO represented more than

401   1,000 pathways. Hence, the RO_2+NO pathways were further elaborated. Table S2 lists the top

402   10 pathways of RO_2+NO that contributed to O_3 production on episodes and non-O_3 episodes at

403   WSI. Clearly, CH_3O_2+NO was the main pathway of RO_2+NO, accounting for 31% (production

404   rate: 0.9 ± 0.2 ppbv h^{-1}) on episodes and 46% (0.5 ± 0.1 ppbv h^{-1}) on non-O_3 episodes,

405   respectively. In addition, the reactions of C_2 radicals with NO contributed to 16% (0.4 ± 0.1

406   ppbv h^{-1}, episodes) and 12% (0.1 ± 0.02 ppbv h^{-1}, non-O_3 episodes), whereas the RO_2 radicals

407   generated from aromatics occupied 10% (0.3 ± 0.1 ppbv h^{-1}, episodes) and 6% (0.07 ± 0.01 ppbv

408   h^{-1}, non-O_3 episodes). In total, the 10 reaction pathways accounted for 57% and 64% of the

409   total pathways of RO_2+NO on episodes and non-O_3 episodes, respectively.

410   In contrast, the reactions of OH+NO_2 and O_3 photolysis were the major contributors to O_3

411   destruction on O_3 episode days with an average destruction rate of 0.9 ± 0.2 ppbv h^{-1} (52%) and

412   0.5±0.1 ppbv h^{-1} (29%), respectively, while O$_3$ photolysis made the highest contribution on

413   non-O$_3$ episode days (destruction rate: 0.3±0.1 ppbv h^{-1}; relative contribution: 50%), followed

414   by the reactions of OH+NO$_2$ (0.1±0.1 ppbv h^{-1}; 23%). The different contributors to the O$_3$

415   destruction were mainly attributed to higher NO$_2$ level during episodes, which facilitated the

416   production of HNO$_3$ via the terminal reaction of OH and NO$_2$. Besides, the reactions of

417   O$_3$+HO$_2$, O$_3$+OH, and the ozonolysis of unsaturated VOCs made minor contributions (17%, 6%

418   and 4% for non-O$_3$ episodes; 10%, 7% and 2% for episodes, respectively) to the O$_3$ destruction

419   due to the lower reaction rates of O$_3$ with radicals and alkenes (< 0.1 ppbv h^{-1} for non-episodes

420   and < 0.2 ppbv h^{-1} for episodes).
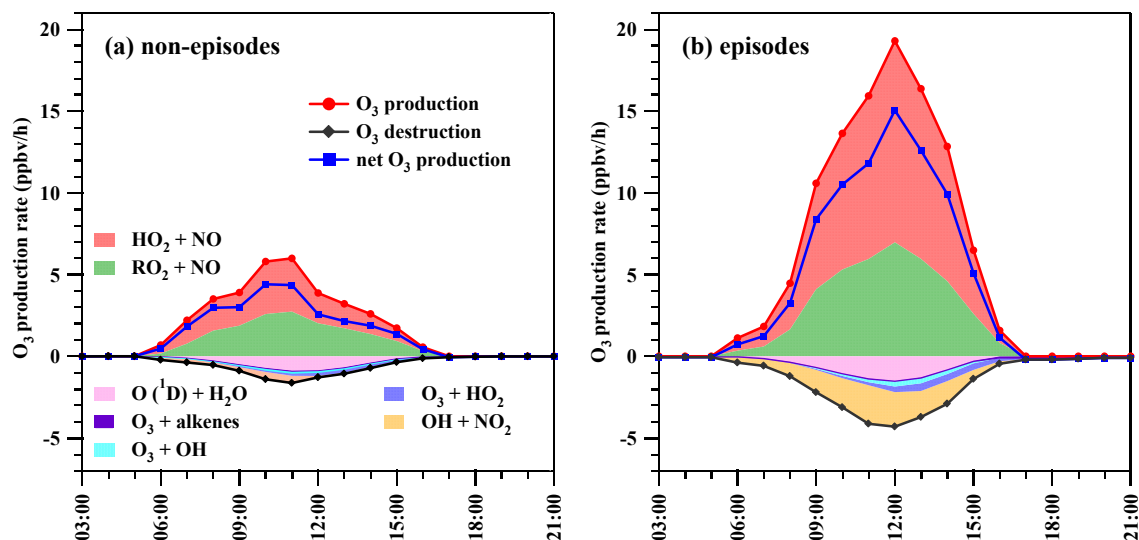

421

422   Figure 6. Breakdown of simulated O$_3$ production and destruction rates at WSI on (a) non-O$_3$

423   episodes and (b) episodes. The total production, total destruction and net production rates are

424   red, black and blue lines, respectively.

425   3.4.3 Impact of VOCs on O$_3$ formation pathways

426   After the most sensitive VOC species to O$_3$ formation were identified by RIR value, the impact

427   of these selected VOCs on O$_3$ formation pathways was investigated in detail. As discussed

428   above, a VOC species can affect the O_3 formation by not only producing RO_2 radicals through

429   reactions with OH, but also generating HO_2 via the cycling processes (SR-10 in Text S1). Thus

430   the pathways of VOCs contributing to O_3 formation can be categorized into two reactions:

431   RO_2+NO and HO_2+NO.

432   (1). RO_2+NO pathway:

433   Figure 7 displays simulated contributions of the top 10 VOC species (determined by their RIR

434   values and these 10 VOCs included 9 top AVOC and isoprene) to O_3 formation pathways at

435   WSI during episodes and non-O_3 episodes. The simulated contribution of each VOC was

436   calculated from the difference between two scenarios. One was called "base case", in which all

437   measurement data was input into the PBM-MCM model. The other was "constrained case",

438   which also used all measurement data but excluded the selected one VOC as input. Hence, the

439   contribution of each individual VOC to O_3 formation pathways was obtained from the

440   difference between the output of the "base case" and the related "constrained case" (see Eq. 6

441   in the footnote of Tables S3 and S4, respectively). In addition, the contributions of the top 10

442   VOC species to the variations of radicals and NO_x are also specified in Table S3 (for O_3

443   episodes) and Table S4 (for non-O_3 episodes). During episodes, toluene made the largest

444   contribution to RO_2+NO pathway (9.6%), followed by formaldehyde (9.1%) and acetaldehyde

445   (8.6%) (Figure 7a). In total, the contributions of the 10 major VOCs accounted for 53.6% of

446   the pathway of RO_2+NO. In comparison, during non-O_3 episodes, trimethylbenenze and xylene

447   made the main contributions to RO_2+NO, with a percentage of 4.9% and 4.8%, respectively,

448   followed by toluene (4.2%) and isoprene (3.6%) (Figure 7b). The total contributions of the 10

449   major VOCs only accounted for 25.4% of the pathway of RO_2+NO. The positive contributions

450   of most VOCs to RO_2+NO pathway can be explained by the variations of radicals and NO. In

451   Tables S3 and S4, it was found that all RO_2 and most HO_2 increased, while all NO and most

22

452 OH decreased. Taking toluene as an example (Row 1 in Table S3), toluene consumed OH to

453 produce RO_2 (SR-6 in Text S1), thus OH decreased 2.9% and RO_2 increased 16.7%. Further

454 conversion of RO_2 to HO_2 (SR-10) caused an increase of HO_2 (9.3%). Since both RO_2 and HO_2

455 consumed NO to produce O_3 (SR-10 and SR-1), NO decreased 3.5%. Thus, the largely

456 increased RO_2 and insignificantly decreased NO resulted in an increasing contribution of

457 toluene to RO_2+NO pathway (9.6%). However, it is worth noting that formaldehyde made a

458 negative contribution to the pathway (-1.5%). According to the reaction SR-12, the reaction of

459 HCHO and OH produced HO_2 and CO directly. HCHO only influences RO_2 indirectly through

460 reactions SR-1 and SR-6. Indeed, with regard to the contribution of HCHO (Row 10 in Table

461 S4), HO_2 increased 12.4% (SR-11 and SR-12) and RO_2 only increased 4.1%, while more NO

462 was consumed (9.6%). The largely decreased NO and insignificantly increased RO_2 led to a

463 decreasing contribution of HCHO to RO_2+NO pathway, presenting a negative contribution.

464 (2). HO_2+NO pathway:

465 During episodes, HCHO dominated the contribution to HO_2+NO (18.3%), since HCHO

466 directly produces HO_2 through its photolysis and the reactions with OH (SR-11 and SR-12)

467 (Figure 7a). However, the contributions of other VOCs were less than 5%. The total

468 contributions of the 10 major VOCs accounted for 36.1% of the pathway of HO_2+NO.

469 In comparison, during non-O_3 episodes, it was found that most VOC species made negative

470 contributions to HO_2+NO pathway (Figure 7b). Acetaldehyde made the most negative

471 contribution (-4.5%), followed by trimethylbenenze (-3.2%), xylene (-1.8%) and toluene (-

472 1.7%). As the conversion of RO_2 to HO_2 was limited by NO during non-O_3 episodes (SR-10),

473 the increase of RO_2 caused little change of HO_2 (See Table S4). Again, using toluene as an

474 example (Row 3 in Table S4), RO_2 increased 7.2% and NO decreased 3.1%, while HO_2 only

475 increased 0.4%. With the little changed HO_2 and a decreased NO, the contributions of most

476 VOCs to the pathway of HO_2+NO decreased, leading to a negative contribution. Nevertheless,

23

477 two species had positive contributions to the HO_2+NO pathway. HCHO dominated the

478 contribution of HO_2+NO (5.5%), followed by ethene (1.1%). Since HCHO produced HO_2

479 directly, it is not surprising to see its contribution to the HO_2+NO pathway. The minor

480 contributions from ethene were due to the chemical characteristics of alkenes. That is, OH

481 radicals are added to its double bond and are not abstracting a hydrogen atom from ethene to

482 produce $HOCH_2CH_2O_2$ radicals (SR-19 in Text S2) (Seinfeld and Pandis, 2006). Furthermore,

483 the $HOCH_2CH_2O$ radicals, products of $HOCH_2CH_2O_2$+NO (SR-20), are easy to decompose

484 (SR-21) and react with O_2 (SR-22, 23) to produce HCHO and HO_2 radicals. The overall

485 reactions (SR-19-23) can be simplified as (Seinfeld and Pandis, 2006):

486 $\qquad C_2H_4 + OH\cdot + NO \xrightarrow{3O_2} NO_2 + 1.44 \text{ HCHO} + 0.28 \text{ HOCH}_2\text{CHO} + HO_2\cdot \qquad$ (R-1)

487 Similarly, propene (the 11th species during episodes, figure not shown) followed the reaction

488 (R-1) with less HCHO produced (the constant was 1.3), resulting in positive but lower

489 contribution to HO_2+NO (0.1%). Overall, although HCHO and ethene made positive

490 contributions to HO_2+NO, the total contribution of the 10 major VOCs was negative,

491 accounting for -7.8% of the pathway of HO_2+NO on non-O_3 episodes.

492

493
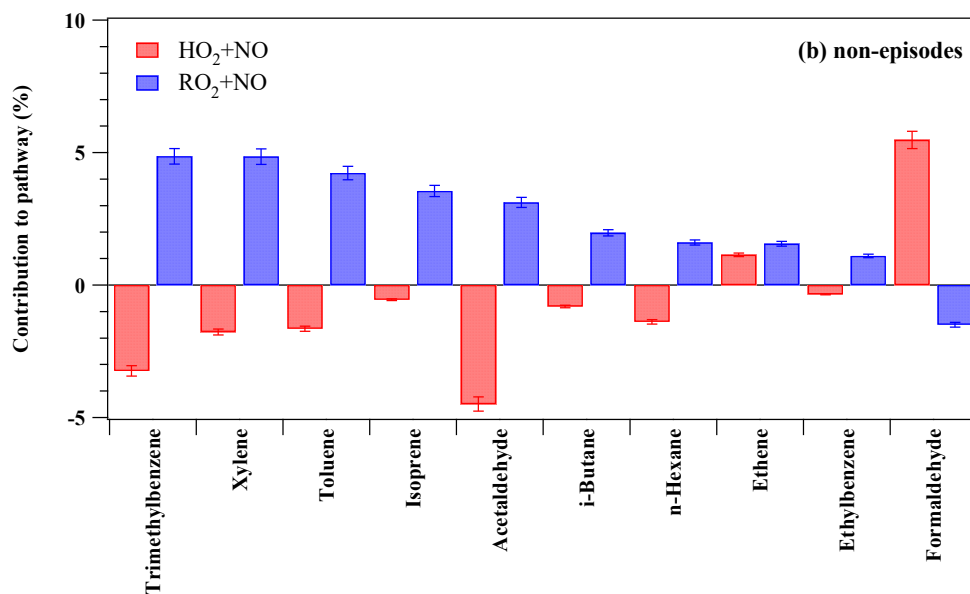

Figure 7. Simulated contributions of top 10 VOC species to O_3 formation pathways at WSI during (a) O_3 episodes and (b) non-O_3 episodes. The top 10 VOC species are determined by their RIR values. Error bars represent 95% confidence interval of the averages.

4 Conclusions

A PBM-MCM model, driven with the observation data obtained in autumn 2013, was used to investigate O_3 photochemistry at WSI over the SCS. Unlike previous studies undertaken in

500   continental areas of the study region, this study for the first time attempted to understand the

501   O_3 photochemistry over the marine environment under the influence of continental emissions.

502   Compared to non-O_3 episodes, the levels of O_3 and its precursors were significantly higher

503   during episodes. The simulated results revealed that the O_3 formation was VOC-limited on

504   episode days but more sensitive to NO_x during non-O_3 episodes, implying that controlling NO_x

505   emissions during non-episode days was more effective to O_3 reduction, while cutting VOC

506   emissions on episode days mitigated O_3 formation over the SCS. It was found that the summed

507   RIR values of top 10 AVOC species accounted for 77% of the total RIRs, indicating that O_3

508   formation over the SCS was mainly caused by a few VOC species, especially OVOCs, and the

509   control measures should focus on these species to reduce the O_3 pollution. Analysis of O_3

510   photochemistry showed that the average OH mixing ratio was $4.2 \pm 1.1 \times 10^6$ molecules cm^{-3}

511   during episodes and $2.5 \pm 0.8 \times 10^6$ molecules cm^{-3} on non-O_3 episode days, reflecting higher

512   photochemical reactivity on episode days. In addition, both the production and loss rates of OH

513   and HO_2 were higher on episodes, suggesting more efficient radical cycling, which led to the

514   O_3 production greater than the O_3 destruction on both episode and non-O_3 episode days,

515   indicative of net O_3 production with a rate of 5.7 ± 1.1 ppbv h^{-1} on episode days and 1.8 ± 0.4

516   ppbv h^{-1} on non-O_3 episode days. Moreover, photochemistry of toluene and trimethylbenzene

517   made the highest contribution to the pathway of RO_2+NO during episodes and non-O_3 episodes,

518   respectively, while HCHO chemistry dominated the contribution to HO_2+NO pathway on both

519   episodes and non-O_3 episode days. These findings advanced our knowledge on the O_3

520   photochemistry over the SCS.
