26   **Abstract**

27   From manufacturing onset through service, cure progress and structural integrity of fibre-

28   reinforced polymer (FRP) composites are monitored continuously using a single type of

29   pre-implanted nanocomposite sensors. The sensors precisely respond to broadband

30   dynamic strains up to half a megahertz, yet without imposing intrusion to host composites

31   and downgrading the original structural integrity. In conjunction with differential scanning

32   calorimetry and a Sesták–Berggren autocatalytic kinetic model, cure behaviors of FRPs

33   during fabrication are evaluated accurately, in terms of the matrix polymerization degree

34   that is correlated with subtle changes in propagation characteristics of guided ultrasonic

35   waves captured by the pre-implanted sensors. Use of the sensors is subsequently extended

36   to structural integrity monitoring of FRPs that are in service. Experimental validation

37   demonstrates that a transient impact to composites can be localized and imaged with the

38   pre-implanted sensors. This study illustrates an *in situ* life cycle monitoring approach for

39   FRPs using a single type of permanently implanted sensors with neglectable intrusion to

40   composites.

43   monitoring

1. Introduction

Real-time, continuous condition monitoring of fibre-reinforced polymer (FRP) composites, from the manufacturing onset, through service to the end of life, is of vital significance, to warrant structural integrity, reliability and durability spanning the entire life cycle of composites [1-3]. To accommodate such a need, prevailing approaches use multiple types of sensors with distinct sensing philosophies, to monitor different life cycle stages [1-3], yet the use of a single type of sensor for uninterrupted monitoring across multiple stages is increasingly attempted. As representative examples, Rufai *et al.* [4] and Nielsen *et al.* [5], respectively, developed optical fibre sensing networks to estimate strain accumulation in large-scale composites during manufacturing, and subsequently to measure strain variation using the same sensors when composites are subject to loadings in service. Notwithstanding, fibre optics-based sensors are of excessive thermal susceptibility to the ambient temperature fluctuation, restricted by which fibre optics-based sensors are usually used for monitoring cure progress of FRPs under an isothermal condition [6]. Contrast to this, optical fibres are, however, not sensitive to the presence of damage in FRPs that is distant, because such type of sensors can only perceive localized strain variation in sensor vicinity which is not remarkably affected by distant damage. The brittle nature of optical fibres entails extra caution during sensor embedding, adding extra complexity to FRP fabrication [7]. More importantly, optical fibres – a passive sensor, can only facilitate passive monitoring of strain changes in a relatively low-frequency regime.

Lead zirconate titanate (PZT)-made sensors respond to dynamic strains in a broad band, with proven sensing capability to entertain acousto-ultrasonics-based monitoring [8, 9]. PZT-type sensors can be immobilized with FRPs in either a surface-mounting or an internal-embedding manner, while the latter is preferred when isolation of sensors from

69   environmental attacks (*e.g.*, moisture and corrosion) or reliability of long-term signal

70   acquisition is a concern. There is rich supply of approaches using embedded PZT wafers to

71   implement cure monitoring or structural health monitoring (SHM) of FRPs [10, 11]. To

72   name but a few, Liu *et al.* [10] evaluated the reaction progress of epoxy using embedded

73   PZT wafers, and identified in-service damage in composites in terms of feature changes in

74   guided ultrasonic waves (GUWs) captured by the same PZT wafers. This study endows

75   conventional FRPs with the capacity of self-monitoring, in a continuous and promising

76   manner. However, it is envisaged that when PZT-type sensors are embedded in FRPs,

77   these sensors downgrade, to a certain degree, the composites' original structural integrity

78   [12, 13]. To put it into perspective [13], the reduction in flexural and compression

79   strengths of a FRP, due to the embedment of a PZT wafer, can be as high as 8% and 12%,

80   respectively.

81

82   Recent advances in nanomaterials have offered new possibility to revamp the monitoring

83   philosophy of FRPs through a life cycle, with minimized intrusion to composites due to

84   sensor embedment [14-16]. Luo *et al.* [17, 18] decorated glass fibres with carbonaceous

85   nanomaterials to calibrate the impedance of glass fibre-reinforced polymer composites, on

86   which basis the polymer cure progress was evaluated. The cure monitoring was followed

87   with failure prediction using the same developed fibre sensors when the composites were

88   loaded. In addition to the above fibre sensors, Wang *et al.* [19] and Wang *et al.* [20]

89   respectively developed a laser-induced graphene-based sensor which can be integrated in

90   composites to perform through-life monitoring of structural integrity, with additional

91   merits such as fire retardancy and the function of de-icing. In a similar vein, Lu *et al.* [21]

92   and Ali *et al.* [22] also, respectively, demonstrated the efficiency of using buckypaper and

93   graphene-coated fabrics for process monitoring via measuring the variation in electrical

94 resistance. The principle of both cure evaluation in fabrication and integrity monitoring in

95 service was based on the premise that the change in resin consolidation or the occurrence

96 of damage alters the electrical resistance measured by the nanomaterial-based sensors.

97 Prevailing approaches in this category are limited to the use of polymer composites with

98 dielectric reinforcements (*e.g.*, glass, aramid or nylon fibres), in which short-circuit of

99 sensors by fibres is not an issue. In addition, electrical resistance is a global parameter,

100 only qualitatively and holistically reflecting the alteration in material properties between a

101 pair of electrodes. Though several studies [23, 24] have demonstrated that the electrical

102 impedance tomography is an efficient monitoring approach, the sensitivity of such a

103 technique, when it is used for quantitative evaluation of micro-scale damage, still needs

104 further proof.

105

106 In contrast to electrical impedance, GUWs of higher frequencies carry fairly localized

107 information that is accumulated along wave propagation paths, able to quantitatively

108 estimate cure progress (during manufacturing) or integrity degradation due to damage (in

109 service) even if the damage is distant from the sensor or of microscale [25, 26]. As

110 commented earlier, conventional GUW-based monitoring is regularly implemented in

111 conjunction with the use of PZT-type sensors for GUW generation and acquisition,

112 embedment of which unavoidably degrades the original structural integrity of host

113 composites. On the other hand, the majority of nanocomposite/nanomaterial-based sensors

114 are engineered to perceive quasi-static or low-frequency cyclic strains [27]. He *et al.* [28]

115 recently reported a new genre of one-dimensional, graphene-enabled fibre electronic,

116 which can faithfully capture ultrasonic signals of the frequency up to ~20 kHz. However,

117 there is still limited endeavor to develop implantable sensors that are able to respond to

118 GUWs of several hundred kilohertz or even megahertz.

119   In such a backdrop, we expand our continued endeavour in developing nano-engineered

120   sensors for GUW-based SHM [29-32]. A genre of nanocomposite sensors is tailor-made, to

121   respond to GUWs of half a megahertz. The sensors are pre-implanted in FRPs, with which

122   cure progress calibration during manufacturing and integrity monitoring in service of FRPs

123   are hierarchically implemented, by scrutinizing subtle changes in propagation

124   characteristics of GUWs perceived by the sensors. With differential scanning calorimetry

125   (DSC) and a Sesták–Berggren autocatalytic kinetic model, cure behaviors of composites

126   are evaluated continuously, in terms of the matrix polymerization, to different degree of

127   which GUWs manifest various propagation traits. Use of the pre-implanted sensors is

128   subsequently expanded to structural integrity monitoring, in which a transient impact to

129   composites is localized and imaged. GUW-based continuous monitoring of FRPs spanning

130   from manufacturing to service, in a real-time and *in situ* manner, is achieved using a single

131   type of permanently implanted sensors, yet without sacrificing the original structural

132   integrity of host FRPs.

133

134   **2. Cure Kinetics of Matrix**

135   Material properties of FRPs (*e.g.*, stiffness and strength) are associated with the cure

136   degree of matrix in a curing process [33]. On the other hand, propagation attributes of

137   GUWs in FRPs are also dependent on material properties (*e.g.*, density and stiffness) and

138   geometric features of FRPs [34]. Provided that the density and geometric features of a

139   FRP, and the properties of fibres remain unchanged through the curing process [8, 35], the

140   change in propagation characteristics of GUWs can reflect the cure information of matrix.

141

142   To develop such a correlation, cure behaviors of FRPs are first investigated via DSC and a

143   Sesták–Berggren autocatalytic kinetic model. Without loss of generality, a unidirectional

144 E-glass epoxy prepreg (Guangwei Composites® G15000; thickness: 0.15 mm; fibre weight:

145 150 gsm; resin content: ~40 wt.%) is characterized with a differential scanning calorimeter

146 (METTLER TOLEDO® DSC 3) in a nitrogen atmosphere (20 sccm) at the heating rate (β

147) of 1.0, 1.5, 2.0, 3.0, and 4.5 K/min, respectively, in a temperature range from 298.15 to

148 523.15 K. Prepreg sample (~2 mg) is sealed in an aluminum DSC pan, and placed in the

149 DSC chamber, along with another empty DSC pan that is heated simultaneously for

150 benchmarking.

151

152 The DSC curves (*viz.*, heat flow *vs.* heating temperature) of the prepreg, representing the

153 cure progress of matrix, obtained at representative heating rates, are compared in **Fig. 1**, in

154 which an exothermic peak is observed in each curve. As β increases, the exothermic peak

155 shifts to a higher temperature range with a higher magnitude of exotherm, which is

156 attributable to a higher increasing rate of the temperature.

157

158 With results in **Fig. 1**, the cure degree against time, $\alpha(t)$, is defined as

159
$$\alpha(t) = \frac{H(t)}{H_T},$$
(1)

160 where $H(t)$ is the reaction enthalpy released till a moment of investigation t; H_T signifies

161 the total reaction enthalpy which is to be obtained by integrating the heat flow over the

162 entire exothermic peak area in **Fig. 1**.

163

164 The cure rate, $\frac{d\alpha(t)}{dt}$, can be correlated to the ambient temperature T through curing [36,

165 37] as

166
$$\frac{d\alpha(t)}{dt} = k(T) \cdot f(\alpha),$$
(2)

167 where $k(T)$ denotes a temperature-dependent constant, and $f(\alpha)$ the function representing

168 a kinetic model (to be detailed in the sequent section). $k(T)$ can be expressed using an

169 Arrhenius equation [38] as

170
$$k(T) = A \cdot e^{\frac{-E}{RT}}, \tag{3}$$

171 where A represents a pre-exponential factor, E the apparent activation energy, and R the

172 universal gas constant (8.314 J·mol^{-1}·K^{-1}). With above correlations, **Eq. (2)** can be re-

173 written as

174
$$\frac{d\alpha(t)}{dT} = \frac{A}{\beta} \cdot e^{\frac{-E}{RT}} f(\alpha). \tag{4}$$

175 To estimate E and A, the Kissinger method [38, 39] is recalled. The method assumes that

176 the cure degree of resin, regardless of β, remains the same when $\frac{d\alpha(t)}{dt}$ reaches its

177 maximum, on which basis one has

$$\ln(\frac{\beta}{T_p^2}) = \ln(\frac{AR}{E}) - \frac{E}{RT_p}, \tag{5}$$

178

179 where T_p is the temperature, at which $\frac{d\alpha(t)}{dt}$ reaches its maximum at a given β. Via

180 plotting $\ln(\beta/T_p^2)$ versus $1/T_p$, calculating the slope of linear fit and determining the y-

181 intercept, the values of E and $\ln A$ are obtained as 86.26 kJ/mol and 24.87 ln(min^{-1}),

182 respectively, as shown in **Fig. 2(a)**.

183

184 With known E and $\ln A$, the Sesták–Berggren model [37-39] is applied, in conjunction with

185 the obtained DSC results in **Fig. 1**, to ascertain $f(\alpha)$. With the Sesták–Berggren model,

186 $f(\alpha)$ is approximated by

187
$$f(\alpha) = \alpha(t)^m (1 - \alpha(t))^n, \tag{6}$$

188   where *m* and *n* are two unknown variables to be determined. Substituting **Eqs. (6)** into **(4)**

189   and taking the logarithm of the equation, it yields

$$\ln(\frac{d\alpha(t)}{dt}e^{\frac{E}{RT}}) = n \cdot \ln[\alpha(t)^p(1-\alpha(t))] + \ln A, \tag{7}$$

191   where $p = \dfrac{m}{n}$. On the other hand, introducing $\alpha(t)_M$ which represents the cure degree, at

192   which $\dfrac{d\alpha(t)}{dt}e^{\frac{E}{RT}}$ reaches its maxima at a given β (as indicated in **Fig. 2(b)**), *p* can be

193   calculated via

$$p = \frac{\alpha(t)_M}{1-\alpha(t)_M}. \tag{8}$$

195   In **Fig. 2(b)**, it can be seen that for all β of investigation, $\alpha(t)_M$ remains a constant of

196   ~0.3, and *p* is therefore ~0.43. With it, *n* and *m* are further calculated, in **Table 1**. With all

197   parameters in **Table 1**, the correlation between $\dfrac{d\alpha(t)}{dt}$ and cure temperature, and the

198   correlation between $\alpha(t)$ and cure temperature are fitted with the Sesták–Berggren model,

199   and shown in **Fig. 3**. These two correlations can be extended to calculate the cure rate

200   ($\dfrac{d\alpha(t)}{dt}$), and the cure degree ($\alpha(t)$) against the cure temperature, at a given heating rate (

201   β).

202

203   On the other hand, different cure degrees of matrix modulate propagation characteristics of

204   GUWs in FRPs distinctly. Facilitated by the correlations in **Fig. 3**, $\alpha(t)$ can thus be linked

205   to the group velocity (C_g) of GUWs, by taking into account different heating rates (β).

206   With measured C_g, the cure degree can be evaluated (in **Section 3.2**).

207

208

209 **3. Continuous Monitoring of Cure Progress and Structural Integrity**

210 By virtue of the cure kinetic model and the correlation between GUW features and cure

211 degree, monitoring of cure progress of FRPs during manufacturing and structural integrity

212 in service is implemented continuously and hierarchically, using pre-implanted

213 nanocomposite sensors.

214

215 **3.1 Fabrication of Implantable Nanocomposite Sensors**

216 A new sort of piezoresistive nanocomposite sensors is developed via spray coating – a

217 cost-effective additive manufacturing approach. To prepare the sprayable nanocomposite

218 ink, graphene nanoplatelets (GNPs) (TANFENG®; thickness: ~1 nm; diameter: ~50 μm;

219 SSA: ~1200 m^2/g; and purity: >99 wt.%) and polyvinylpyrrolidone (PVP) (Sigma-

220 Aldrich® PVP K-30) are dissolved in 20 ml ethanol, at a weight ratio of 1:19 (0.05 g and

221 0.95 g, respectively). The sensors, with a planar dimension of 20×3 mm^2 each, are

222 deposited on a partially pre-cured B-stage epoxy film using an airbrush. The epoxy film is

223 pre-cured to achieve the cure degree of ~0.4, so that possible flowing of epoxy can be

224 restrained, and the initial morphology of nanocomposite ink deposited on the film can be

225 remained. To minimize intrusion to host FRPs, the sensors are electrified using highly

226 conductive carbon nanotube film (CNT-film)-made wires (DexMat®; linear resistance:

227 20 ± 3 Ω/m; thickness: 10 ± 5 μm; width: 1 ± 0.1 mm). Another layer of epoxy film is placed

228 on the sensors and CNT-film-made wires. Both epoxy films, respectively atop and beneath

229 the sensors and wires, work as a pair of dielectric membranes to encapsulate the sensors

230 and insulate them from conductive fibres (*e.g.*, carbon fibre) when implanted into FRPs.

231 The encapsulated sensors are entirely cured under a vacuum-assisted cure condition (130

232 °C, 60 min). A batch of finished sensors is photographed in **Fig. 4**. Scanning electron

233 microscopy (SEM) images of a sensor are shown in **Fig. 5**. In **Fig. 5(a)**, the thickness of

234   sensor including its wires is measured to be ∼45 μm only; in **Fig. 5(b)**, GNPs are observed

235   to disperse in PVP matrix evenly – a critical merit to enhance the sensitivity of

236   piezoresistive sensors to high-frequency dynamic strains (*e.g.*, GUWs).

237

238   To interrogate the possible intrusion of implanted sensors to the host FRP composites,

239   sensors are implanted between the 4th and 5th plies of an eight-ply quasi-isotropic

240   $[0/90/45/-45]_s$ FRP laminate, which is then cured in accordance with a standard

241   autoclaving process with key parameters listed in **Table S1**. Tensile and bending tests, in

242   accordance with ASTM D3039 and D790 respectively, are conducted to gauge the

243   degradation in mechanical attributes of FRPs due to sensor intrusion. For each category of

244   test, three FRP specimens, each of which is implanted with a nanocomposite sensor, along

245   with another three specimens which are of the same dimensions but without sensor

246   implantation, are tested. **Figure S1** displays the mechanical test results of FRPs with and

247   without the implanted sensor. Both the stress-strain curves (acquired in the tensile test) and

248   the load-displacement curves (acquired in the bending test) demonstrate that the implanted

249   sensor does not result in measurable degradation in elastic attributes of the host

250   composites, before the specimen fracture. Neglectable change in tensile and flexural

251   strengths is observed: the tensile strength decreases slightly from its original 845.9±15.38

252   MPa to 823.5±17.41 MPa upon implantation of sensors, and the flexural strength increases

253   marginally from 916.6±30.35 MPa to 950.9±67.49 MPa (the slight increase is attributable

254   to the discrepancy among tested specimens). **Figure 6** shows the cross-section of laminate

255   with an implanted sensor (including its CNT-film-made wires), insert of which highlights

256   the sensor vicinity and accentuates the excellent interface between prepreg and sensor. The

257   mechanical test results have demonstrated the high compatibility of the implanted sensors

258   with the host composites.

259 Responsivity of the implanted sensors to quasi-static tensile loads and high-frequency

260 GUWs is respectively calibrated (detailed experimental configuration in **Section 3.2.1**).

261 The nanocomposite sensors, by virtue of the quantum tunnelling effect [40, 41],

262 demonstrate sufficient sensitivity to dynamic strains in a broad band, ranging from static

263 tensile loads (with a gauge factor of 34.5), as shown in **Fig. S2(a)**, to GUWs up to 450

264 kHz, in **Figs. S2(b)** and **(c)**.

265

266 **3.2 Cure Monitoring**

267 With the Sesták–Berggren model, the matrix cure degree ($\alpha(t)$) is correlated with group

268 velocity (C_g) of GUWs perceived by the pre-implanted sensors, and the cure progress of

269 FRPs can be monitored in a real-time and *in situ* manner.

270

271 **3.2.1 Methodology**

272 Eight plies of unidirectional E-glass epoxy prepregs are stacked to produce an 8-layer

273 quasi-isotropic [0/90/45/-45]$_s$ FRP laminate ($500 \times 500 \times 1.15$ mm^3). A group of eight

274 nanocomposite sensors is implanted between the 4th and 5th prepregs, to configure a sparse

275 sensor network via CNT-film-made wires. The sensor network is instrumented with a self-

276 developed signal generation and acquisition system, as illustrated schematically in **Fig. 7**.

277 Two ETFE peel films (AIRTECH$^®$ WL5200B), 15 μm thick each, are placed atop and

278 beneath the stacked prepregs. The stacked prepregs that are sandwiched by the peel films

279 are placed on an aluminium tooling plate covered with a layer of thick breather. A

280 miniaturized PZT wafer (PSN-33; Ø: 12 mm; 1 mm thick) is surface-placed at the centre of

281 the upper peel film for GUW generation, which is 150 mm from each of the eight

282 nanocomposite sensors. Under the vacuum pressure of -25 inHg, a good acoustic coupling

283 is achieved between the PZT wafer and prepregs, warranting efficient generation and

284   transmission of GUWs. After adding another thick breather layer on the upper peel film,

285   the prepregs undergo a standard vacuuming process. Upon vacuuming, prepregs are heated

286   from 298.15 to 458.15 K until the laminate is fully cured.

287

288   A 5-cycle Hanning-function-modulated sinusoidal toneburst is generated at a frequency of

289   175 kHz every ten microseconds, using a waveform generator on NI® PXIe-1071 platform.

290   The generated signal is applied on the PZT wafer, after it is amplified to 400 V_{p-p} via a

291   linear power amplifier (Ciprian® US-TXP-3). Propagation of the generated GUWs in

292   prepregs during the cure progress is perceived with the pre-implanted sensors and recorded

293   with an oscilloscope (Agilent® DSO9064A), as shown in **Fig. 7**.

294

295   **3.2.2 Results**

296   All GUW signals recorded as cure progresses are applied with a first-order Butterworth

297   filter to mitigate ambient noise and measurement uncertainties. **Figure 8** shows

298   representative GUW signals perceived by a pre-implanted sensor, along with the energy

299   envelopes of signals obtained via the Hilbert transform, at different temperatures with the

300   heating rate of 1.5 K/min. The Hilbert transform is an approach to canvass a signal in the

301   time domain in terms of its energy distribution, and the envelope depicts the signal energy

302   migration against time. It can be seen in **Fig. 8** that both the group velocity of GUWs and

303   signal amplitudes change remarkably against temperature through curing.

304

305   The group velocity of the zeroth-order symmetric Lamb wave mode (denoted by S_0 in

306   figures) is extracted from signals, with which the cure progress of matrix is real-time

307   monitored according to the Sesták–Berggren model. C_g is calculated in virtue of the time at

308   which the signal energy envelope reaches its peak, as

309
$$C_g = \frac{L}{t_s - t_e},$$
(9)

310 where L (150 mm) is the distance between the PZT wafer and a nanocomposite sensor. t_e

311 and t_s signify the moments, at which the energy envelope reaches its peak, respectively for

312 the excitation signal and for the sensor-received signal.

313

314 A batch of 8-layer prepregs, each with the pre-implanted nanocomposite sensor network

315 and a surface-placed PZT wafer, is prepared. As representative results, for each heating

316 rate (namely 1.0 and 1.5 K/min), two groups of measured signals are displayed in **Fig. 9**,

317 showing the progressive alteration in C_g of the S_0 wave mode through a curing process.

318 The S_0 wave mode is measurable at the beginning of cure. As observed, C_g of the S_0 wave

319 mode decreases, as the cure temperature elevates, until wave signals can no longer be

320 identified due to the fact that the matrix becomes a highly attenuative, viscous liquid; as

321 cure continues, the S_0 wave mode is measurable again from ~393 K for the heating rate of

322 1.0 K/min, and from ~399 K for 1.5 K/min, at which the corresponding cure degrees are

323 0.620 (for 1.0 K/min) and 0.625 (for 1.5 K/min), as predicted by the Sesták–Berggren

324 model. These results are consistent with the cure degree at the gel point of the matrix

325 (~0.6) as provided by the manufacturer. As depicted in **Fig. 9**, after the gel point of matrix,

326 C_g of GUWs increases rapidly, as a result of a higher crosslinking density of the resin. The

327 increasing rate of C_g decreases after the matrix begins its vitrification and subsequently

328 remains slight change which indicates the completion of cure.

329

330 The alteration of C_g of the S_0 wave mode is quantitatively associated with the change in

331 stiffness of the matrix which reflects the cure degree, as shown in **Fig. 10**. In **Fig. 10(a)**,

332 good consistence among all experimentally measured C_g is noted when the cure degree of

333   matrix is the same, irrespective of different heating rates. With **Fig. 10(a)**, the correlation

334   between the cure degree of matrix and C_g of the S_0 wave mode is fitted as

335    $$C_g = 1035 \int_{0.625}^{\alpha} \alpha^{0.39} (1-\alpha)^{0.26} d\alpha + 2460 , \qquad \textbf{(10)}$$

336   as shown in **Fig. 10(b)**. With such a correlation, cure information of composites after the

337   gel point of matrix can be monitored in a real-time manner with the pre-implanted

338   nanocomposite sensors, to quantify the cure degree of matrix and indicate the completion

339   of resin cure.

340

341   **3.2.3 Cure Anomaly Detection**

342   With **Eq. (10)**, the cure progress of another two sets of 8-layer prepregs is monitored at the

343   heating rate of 2.0 K/min. To introduce a mock-up anomaly in a curing process, a heating

344   tape (measuring 15×3 cm^2) is adhered at the back surface of the tooling plate for one of

345   the two sets. The tape is located along the GUW propagation path that is linked by the PZT

346   wafer and the nanocomposite sensor I (indicated in **Fig. S3**). The heating tape quickly

347   elevates the temperature of matrix in the vicinity of tape, at a higher heating rate than that

348   in the rest region of matrix. A thermocouple is collocated alongside the tape to real-time

349   record the temperature change in such an abnormal heating area. As seen in **Fig. 11(a)**, the

350   predicted C_g, obtained via the Sesták–Berggren model and also **Eq. (10)**, is consistent with

351   that experimentally measured in the normal heating area of matrix; in contrast, the C_g

352   measured from the abnormal heating area shows inconsistence with the model-predicted C_g,

353   in **Fig. 11(b)**, implying cure anomaly.

354

355

356

357

358   **3.3 In-service Impact Localization**

359   Subsequent to the above cure progress monitoring, structural integrity of the same FRP

360   laminate in service is further evaluated, using the same pre-implanted nanocomposite

361   sensor network. The eight nanocomposite sensors in the network are denoted with S_i (

362   $i = 1, 2, \mathrm{L}, 8$), enclosing a circular inspection area with a radius of 150 mm, **Fig. 7**. As a

363   proof-of-concept validation, a steel ball (Ø: 8 mm; weight: 10 g) impinges on the laminate

364   from a height of 250 mm (~25 × 10^{-3} J impact energy) in a drop-weight impact test, and the

365   impact triggers acoustic emission (AE) signals that are captured by the sensors and

366   recorded with the system. Raw signals are applied with a first-order Butterworth low-pass

367   filter with the cut-off frequency of 10 kHz, to supress measurement noise. A delay-and-

368   sum triangulation algorithm [42] is recalled to image the impact spot. In the algorithm, the

369   moment t_i, at which the first-arrival wave component is captured with the ith sensor located

370   at (x_i, y_i), is defined as

371   $$t_i = t_0 + \Delta t_i , \tag{11}$$

372   where t_0 denotes the moment at which the steel ball impinges on the laminate, and Δt_i the

373   time for the first-arrival wave component in the AE signal to travel from the impact spot to

374   S_i. With another sensor S_j at (x_j, y_j), the difference (*i.e.*, $\Delta t_{ij}(x, y)$) in the arrival time of AE

375   signals captured by S_i and S_j reads

376   $$\Delta t_{ij}(x, y) = t_i - t_j = (t_0 + \Delta t_i) - (t_0 + \Delta t_j) = \frac{\sqrt{(x - x_i)^2 + (y - y_i)^2} - \sqrt{(x - x_j)^2 + (y - y_j)^2}}{v_{plate}} , \tag{12}$$

377   $$(i = 1, 2, \mathrm{L}, 8)$$

378   where variables are distinguished by subscripts i and j for two individual sensors, v_{plate} the

379   velocity of the first-arrival wave component, and (x, y) the impact spot location. A two-

380   dimensional grey-scale image is obtained using the delay-and-sum triangulation algorithm,

381   in which each pixel value ($\xi_{ij}(x, y)$) is defined as

382
$$\xi_{ij}(x, y) = \max(E_i + E_j(\Delta t_{ij}(x, y))) , \qquad\qquad \textbf{(13)}$$

383   where E is the energy packet of the first-arrival wave component extracted from the AE

384   signals. The max operator in the equation defines the maximal of summation of two signals

385   received by S_i and S_j, which is associated with the probability of impact spot – that is the

386   perception as to the impact spot from the perspective of the sensor pair of S_i and S_j.

387   Aggregating images constructed by all sensor pairs rendered by the sensor network, a

388   superimposed image is made, in which those pixels with greater values have a higher

389   degree of probability of the impact spot, and *vice versa*. **Figures 12(a)** and **(b)** show the

390   raw and filtered signals captured by S_3 and S_5, as an example; **Fig. 12(c)** highlights the

391   identified impact location using the above delay-and-sum algorithm, in which the colour

392   gradient calibrates the probability of the occurrence of an impact. A high degree of

393   coincidence between the identified impact spot and reality is observed.

394

395   **4. Concluding Remarks**

396   This study demonstrates a new approach for *in situ*, online monitoring of FRPs using a new

397   kind of implantable nanocomposite sensors, from cure monitoring to in-service impact

398   localization. The pre-implanted sensors, fabricated by spray coating the GNPs/PVP

399   nanocomposite ink on partially pre-cured B-stage epoxy films, are ~45 μm in thickness and

400   demonstrate nonintrusive attributes with the host FRPs, resulting neglectable variation in

401   both tensile (<3%) and flexural (<4%) strengths. Being capable of perceiving strains in a

402   broad frequency range from quasi-static loads (with a high gauge factor of 34.5) to GUWs

403   up to 450 kHz, the sensors endow conventional composites with a capability to self-

404 monitor the matrix cure progress and self-detect the cure anomaly, if any, via interpreting

405 subtle changes in propagation characteristics of sensor-captured GUW signals. The use of

406 the same type of sensors can also be extended to structural integrity evaluation of FRPs

407 when the composites are in service, as proven by the experimental validation.
