1 **Abstract:**

2 In nature, bacteria form biofilms by producing exopolymeric matrix that encase its entire  
3 community. While it is widely known that biofilm matrix can prevent bacterivore predation and  
4 contain virulence factors for killing predators, it is unclear if they can alter predator motility.

5 Here, we report a novel ‘quagmire’ phenotype, where *Pseudomonas aeruginosa* biofilms could  
6 retard the motility of bacterivorous nematode *Caenorhabditis elegans* via the production of a  
7 specific exopolysaccharide, Psl. Psl could reduce the roaming ability of *C. elegans* by

8 impeding the slithering velocity of *C. elegans*. Furthermore, presence of Psl in biofilms could  
9 entrap *C. elegans* within the matrix, with dire consequences to the nematode. After being  
10 trapped in biofilms, *C. elegans* could neither escape effectively from aversive stimuli

11 (noxious blue light), nor leave easily to graze on susceptible biofilm areas. Hence, this  
12 reduced the ability of *C. elegans* to roam and predate on biofilms. Taken together, our work  
13 reveals a new function of motility interference by specific biofilm matrix components, and

14 emphasizes its importance in predator-prey interactions.

15

17 matrix

18

1 **Introduction:**

2 Bacteria colonize most natural surfaces and their hosts as biofilms. The encased community of  
3 bacterial cells produces its extracellular matrix which serves as a barrier from  
4 physicochemical factors [1], and allows bacterial differentiation and specialization [2, 3].  
5 Living in biofilms can offer strong competitive advantages in the presence of various  
6 environmental stresses, such as predation, immune attack and antimicrobials. Depending on  
7 the stimuli and gene regulatory networks, the biofilm matrix is highly complex and dynamic.  
8 For instance, the opportunistic pathogen *Pseudomonas aeruginosa* secretes varying  
9 compositions and levels of exopolysaccharides (Pel, Psl and alginate), adhesion proteins  
10 (CdrA), extracellular DNA (eDNA), allowing it colonize both abiotic and biotic surfaces [4].

11

12 The production of biofilm matrix is mainly mediated by the c-di-GMP secondary messenger  
13 system, which is common in most Gram-negative bacterial species [5]. Synthesis of c-di-GMP  
14 by diguanylate cyclases (DGCs) will lead to biofilm formation via loss of bacterial motility  
15 and induced production of exopolymeric matrix, whereas phosphodiesterase (PDE)-mediated  
16 degradation of c-di-GMP causes biofilm dispersal and production of specific virulence  
17 factors, such as exotoxin A from Type III secretion system (T3SS) and rhamnolipids [6-9].  
18 The redundancy of DGCs and PDEs in *P. aeruginosa* leads to fine-tuning the expression of  
19 various biofilm matrix components. For instance, production of the Pel and Psl  
20 exopolysaccharides is controlled by the *wsp* operon, with WspR as the DGC [10], whereas  
21 MucR controls alginate production [11]. PDEs, such as DipA, are involved in biofilm  
22 dispersal [12], while RocR mediates swarming motility [13].

23

1 In the natural environment, *Caenorhabditis elegans* are bacterivores which roam and feed on  
2 microbial biofilms growing on rotten fruit or plant biomass. As a model organism applicable  
3 to a multitude of research fields encompassing developmental biology, behavioral studies to  
4 infections, *C. elegans* are experimentally grown on bacterial lawns in media plates. While  
5 *Escherichia coli* OP50 are common food choices for *C. elegans*, *Yersinia* biofilms were  
6 previously shown to block the mouth and prevent bacterial uptake by *C. elegans*, resulting in  
7 the nematodes' death by starvation [14]. Furthermore, biofilms formed by *Pseudomonas*  
8 *aeruginosa* [15] and *Salmonella* [16] could produce specific virulence factors, such as  
9 pyoverdine [17], that killed *C. elegans* after being internalized into the intestine. While these  
10 effects mainly revolved around *C. elegans* feeding and intestinal infection, it is unclear if  
11 biofilms can alter motility which is a key feature of *C. elegans*.

12  
13 Here, we report for the first time that the biofilm matrix can alter *C. elegans* locomotion and  
14 its resulting behavior, herein termed as the 'quagmire' phenotype. Using the *P. aeruginosa*  
15 mutant library of known components and regulators for biofilm matrix, we showed that Psl, a  
16 key exopolysaccharide present in the *P. aeruginosa* biofilm matrix, could impede nematode  
17 locomotion, which was adequately reflected in reduced velocity and roaming of *C. elegans*.  
18 Trapping of nematodes in the *P. aeruginosa* biofilm matrix significantly reduced the ability of  
19 *C. elegans* to either escape from a noxious blue-light repellent, or move towards the  
20 susceptible OP50 biofilms.

21  
22 Taken altogether, our study suggests a novel mechanism by which biofilms employ to impede  
23 *C. elegans* movement, possibly to delay predation and boost survival. In the context of

1 bacterial infections, our findings also suggest a plausible similarity in specific biofilm matrix  
2 components impeding immune cell migration.

3

#### 4 **Materials and Methods:**

5

##### 6 *Bacterial strains and growth conditions*

7 The bacterial strains and plasmids used in this study are listed in Supplementary Table S1. *E.*  
8 *coli* DH5a strain was used for standard DNA manipulations. LB medium was used to cultivate *E.*  
9 *coli* and *P. aeruginosa* strains. For plasmid maintenance in *E. coli*, the medium was  
10 supplemented with 100  $\mu\text{g ml}^{-1}$  ampicillin and 15  $\mu\text{g ml}^{-1}$  gentamycin. For marker selection in *P.*  
11 *aeruginosa*, 30  $\mu\text{g ml}^{-1}$  gentamycin, 30  $\mu\text{g ml}^{-1}$  tetracycline or 200  $\mu\text{g ml}^{-1}$  carbenicillin were  
12 used, as appropriate.

13

##### 14 *Growth and maintenance of C. elegans*

15 The bacterial lawn, such as *E. coli* OP50 and *P. aeruginosa* strains, were cultivated on nematode  
16 growth media (NGM) agar plates at 37 °C for 16 hrs. The laboratory *C. elegans* N2 nematode  
17 was transferred to the bacterial lawn on the nematode growth media (NGM) agar plates and  
18 cultivated at room temperature for 72 hrs to allow the population expansion.

19

##### 20 *C. elegans motility assay*

21 All *P. aeruginosa* strains were first inoculated and grew in 2 ml of Luria-Bertani (LB) medium at  
22 37 °C with shaking at 200 rpm for 16 hrs. After washing the overnight culture with 0.9% NaCl,  
23 the 30  $\mu\text{l}$  of bacterial culture was transferred to NGM petri dish (3-cm-diameter) for spreading

1 with a bacteriological spreader. The culture was incubated overnight to allow biofilm growth. At  
2 least 50 individuals of *C. elegans* from 3 independent trials were transferred from the feeding  
3 plate to the centre of the biofilm with titanium wire picker. Unless stated otherwise (such as L1  
4 larvae and adults), L3 *C. elegans* were used for all experiments. The nematodes were given 5  
5 minutes for them to adapt to the fresh environment. Before recording the video, the plate was  
6 tapped for 3 to 4 times to stimulate the *C. elegans* roaming in the bacterial biofilm lawn.

7

### 8 *Track, displacement and velocity analysis*

9 The 30-sec video clip of the locomotion of each single individual was recorded by a  
10 stereomicroscope (Nikon SMZ1270i, Japan) at 10X magnification. The video clips were  
11 processed and analysed with image processing software “ImageJ Fiji”. The locomotion of *C.*  
12 *elegans* each frame was tracked using the manual tracking plugin. The track images were  
13 captured and the frame velocity was calculated by the software in  $\mu\text{m}$  per second. The frame  
14 displacement was calculated in pixels by the formula:

15 
$$\sqrt{\frac{(x_2 - x_1)^2}{(y_2 - y_1)^2}}$$

16  $x_1$ =The initial x-coordinate

17  $x_2$ =The x-coordinate in the next frame of  $x_1$

18  $y_1$ = The initial y-coordinate

19  $y_2$ = The y-coordinate in the next frame of  $y_1$

20

### 21 *Nematode escape assay*

1 The overnight cultures of *P. aeruginosa* strains were inoculated and grown in 2 ml LB medium  
2 at 37 °C overnight with shaking at 200 rpm. The bacterial culture was centrifuged to collect the  
3 cell pellet. The cell pellet was re-suspended with 50 µl 0.9% NaCl. The entire re-suspended  
4 culture was then transferred to the center of the NGM plate to make a concentrated spot  
5 (diameter ~3 mm) for the growth of biofilm trap at 37 °C for 16 hrs. The Stage L3 *C. elegans*  
6 were placed directly onto the biofilm trap. A noxious blue light source from the epifluorescence  
7 microscope (Nikon, Japan) was then used to illuminate the biofilm spot and stimulate the  
8 repulsion of *C. elegans*. The duration of *C. elegans* escaping from the biofilm spot was recorded  
9 using a timer.

10

#### 11 *Food choice assay*

12 As previously described [18], *P. aeruginosa* PAO1 and *E. coli* OP50 lawns (circular shape with  
13 diameter of 1.2 cm) were grown 2.5 cm apart from each other at 37 °C for 16 hrs. After being  
14 washed by PBS buffer twice, 60 nematodes at L3 stage were transferred in the middle between  
15 the lawns of *P. aeruginosa* PAO1 and *E. coli* OP50. The nematodes were incubated at room  
16 temperature, allowing the nematodes to choose their preference between both species. The  
17 number of nematodes on either bacterial lawn was enumerated at 2, 4, 6, 10 and 24 hrs. The  
18 choice index was tabulated as follows: (worm number in PAO1 colonies - worm number in  
19 OP50 colonies) / total worm number used.

20

#### 21 *Biofilm Protection assay*

22 The overnight cultures of *P. aeruginosa* strains and *E. coli* OP50 were inoculated and grown in 2  
23 ml LB medium at 37 °C for 16 hrs with shaking at 200 rpm. The bacterial culture was

1 centrifuged to collect the cell pellet. The cell pellet was re-suspended with 50  $\mu$ l 0.9% NaCl. For  
2 *P. aeruginosa* strains, their cultures were then transferred to the center of the NGM plate to make  
3 a concentrated spot (diameter  $\sim$ 3 mm). On the same plate, OP50 *E. coli* was transferred and  
4 spread with a spreader over the remaining parts of the agar, leaving a 2 mm gap between the *P.*  
5 *aeruginosa* spot and the OP50 lawn. The NGM plate was incubated for 16 hrs at 37  $^{\circ}$ C to allow  
6 the growth of *P. aeruginosa* biofilm which represented the ‘tougher’ biofilm trap and OP50 lawn  
7 the susceptible biofilm.

8

9 On each plate, 5 individual Stage L3 *C. elegans* were transferred and placed onto the *P.*  
10 *aeruginosa* biofilm spot. Alternatively, as controls, *E. coli* OP50 treated with exogenously added  
11 0 or 1  $\mu$ g ml<sup>-1</sup> Pel, Psl were used as biofilm spots. The extent of roaming by the *C. elegans* on  
12 the OP50 lawn after leaving the biofilm spot was quantified by counting the 5 x 5 mm grid  
13 squares being covered by *C. elegans* tracks every 10 minutes till the 60<sup>th</sup> minute. At least 5  
14 replicate plates from 3 independent trials were conducted for the experiment.

15

#### 16 *Reproduction assay of C. elegans on bacterial lawns*

17 To observe if the 5 nematodes could reproduce and expand their population after leaving the *P.*  
18 *aeruginosa* biofilm trap and reaching the OP50 lawn, the plates from the biofilm protection assay  
19 were further incubated at room temperature for 24 hrs to allow the emergence of L1 *C. elegans*  
20 progenies. Only the L1 *C. elegans* progenies on the OP50 lawns were enumerated with a tally  
21 counter.

22

1 Alternatively, when *E. coli* OP50 treated with 1  $\mu\text{g ml}^{-1}$  Pel or Psl were used as biofilm spots,  
2 the plates from the *E. coli* biofilm protection assay were further incubated at room temperature  
3 for 120 hrs to allow the emergence of L1 *C. elegans* progenies. Only the L1 *C. elegans* progenies  
4 on the OP50 lawns were enumerated every 24 hrs with a tally counter. At least 5 replicate plates  
5 from 3 independent trials were conducted for the experiment.

6

### 7 *Exopolysaccharide extraction*

8 As previously described [19], Pel, Psl and alginate were extracted by growing  $\Delta pslBCD/p_{lac}$ -  
9 *YedQ*,  $\Delta pelA/p_{lac}$ -*YedQ* and  $\Delta mucA\Delta pelA\Delta pslBCD$  static biofilms in standard Petri dishes at  
10 37 °C for 16 hrs. The biofilms were collected and separated from the supernatant by  
11 centrifugation at 10000 g for 5 mins. The cell pellet was re-suspended in 0.9% NaCl and treated  
12 with mild water-bath sonication (Elmasonic P120H, Power=50%, Frequency=37 KHz, 5 mins)  
13 to separate the cells from the surface-associated matrix. The cells were then separated from the  
14 matrix by centrifugation, leaving behind the crude matrix extract.

15

16 The crude extract was then further treated by removal of eDNA by precipitation with 25%  
17 ethanol and 0.1 M  $\text{CaCl}_2$ . Extracellular proteins were then removed from the extract with 0.5 mg  
18  $\text{ml}^{-1}$  proteinase K at 60 °C for 1 hr and inactivation at 80 °C for 30 mins. The extract was then  
19 filtered with centrifugal filter (<3 kDa) to remove the metabolites. The extract was then  
20 lyophilized and re-suspended in sterile ddH<sub>2</sub>O.

21

### 22 *Exogenous addition of exopolysaccharides to non-polysaccharide-producing strains*

1 The  $\Delta wspF\Delta pelA\Delta pslBCD$  and  $\Delta mucA\Delta algT$  cells from growth culture (described in the  
2 previous section on growth conditions) were washed with 0.9% NaCl and centrifuged at 13000 g  
3 for 3 mins. Varying concentrations (0, 0.5, 1 and 2  $\mu\text{g ml}^{-1}$ ) of Pel or Psl were mixed and re-  
4 suspended in the  $\Delta wspF\Delta pelA\Delta pslBCD$  cell pellet, while similar procedures were used for  
5 alginate and the  $\Delta mucA\Delta algT$  cell pellet. To test the effects of polysaccharide addition to a  
6 different bacterial species, *E. coli* OP50 was treated with 0 or 1  $\mu\text{g ml}^{-1}$  Pel, Psl or alginate.

7  
8 The 30  $\mu\text{l}$  of bacteria + exopolysaccharide mixture was transferred to NGM petri dish (3-cm-  
9 diameter) for spreading with a spreader. The culture was incubated overnight to allow biofilm  
10 growth. At least 50 individuals of Stage L3 *C. elegans* were transferred from the feeding plate to  
11 the center of the biofilm with a titanium wire picker. The nematodes were given 5 minutes for  
12 them to adapt to the fresh environment. Before recording the video of each nematode, the plate  
13 was tapped for 3 to 4 times to stimulate the *C. elegans* roaming in the bacterial biofilm lawn.

#### 14 15 *Prevalence of Pel and Psl genes in microbial species*

16 The IMG portal [20, 21] was used to search for sequenced microbial species containing Pel and  
17 Psl synthesis genes using (date accessed: 19 Sep 2020). The identified microbial species (*P.*  
18 *aeruginosa*, other *Pseudomonads* and non-*Pseudomonas* species) were enumerated and tabulated  
19 as percentage of total species.

#### 20 21 *Prevalence of mutated WspF protein in sequenced P. aeruginosa strains*

22 The WspF protein sequence of prototypic PAO1 was aligned to that from all sequenced  
23 *Pseudomonas aeruginosa* genomes via the DIAMOND BLASTP tool [22] (date accessed: 22 Jun

- 1 2020). Mismatches with 1 to 6 amino acids were listed, with 750 *P. aeruginosa* sequenced
- 2 genomes being identified.

1 **Results:**

2

3 *Biofilms impede locomotion and restrict roaming of C. elegans*

4 As a proof-of-concept showing that biofilms can impede *C. elegans* and restrict its roaming  
5 behavior, we first need to constitutively elevate c-di-GMP signaling and promote biofilm  
6 formation via the *wsp* operon, which controlled both *pel* and *psl* transcription [10]. We  
7 employed the  $\Delta wsfF$  mutant whose mutation of *wsfF* repressor causes the de-repression of  
8 WspR DGC, resulting in increased biofilm formation via the production of Pel and Psl [10]  
9 (Supplementary Figure S1a). It is important to note that  $\Delta wsfF$  was frequently isolated in *in*  
10 *vitro* and *in vivo* biofilm infections [23, 24]. By aligning the WsfF protein sequence in  
11 prototypic PAO1 to all sequenced *P. aeruginosa* isolates, we also found 750 isolates with 1 to  
12 7 mismatches in the WsfF protein (Supplementary Data S1), indicating the prevalence in  
13 *wsfF* mutations in nature. Furthermore, to confirm that our observations was due to c-di-GMP  
14 signaling *per se* and not attributed to possible pleiotropic effects of the *wsp* operon, we also  
15 expressed the *plac-YedQ* plasmid containing an *E. coli YedQ* DGC in wild-type PAO1 to  
16 constitutively elevate intracellular c-di-GMP levels and boost Pel and Psl production [24].  
17 While cell number in the biofilm mainly remained consistent across the wild-type and  
18 mutants, both  $\Delta wsfF$  and PAO1/*plac-YedQ* produced significantly higher exopolysaccharides  
19 than PAO1 wild-type (Supplementary Figure S2).

20

21 Interestingly, as compared to *E. coli* OP50 (Supplementary Video 1) and wild-type PAO1  
22 (Supplementary Video 2), we observed that the nematodes moved at a slower pace and were  
23 easily trapped in the aggregates formed by  $\Delta wsfF$  mutant (Supplementary Video 3). By

1 tracking the nematodes, we showed a significant reduction in velocity (Figure 1a) and  
2 displacement (Figure 1b) undertaken by the  $\Delta wspF$  mutant as compared to wild-type PAO1.  
3 The nematodes moved constantly, albeit at lower velocity, on  $\Delta wspF$  biofilms, indicating that  
4 they did not stop to rest or adopt punctuated (stop-go) movements (Supplementary Figure S3).  
5 Higher biofilm formation by the  $\Delta wspF$  mutant also significantly restricted the roaming  
6 ability of *C. elegans* to explore the plate, which was reflected by highly localized tracks  
7 (Figure 1c) undertaken by *C. elegans* on  $\Delta wspF$  lawn. Upon closer inspection of the tracks,  
8 we also observed that the nematodes switched between forward and reverse locomotion  
9 frequently on  $\Delta wspF$  lawn, as compared to that of wild-type PAO1 lawn where the nematode  
10 moved in a linear direction (Figure 1c).

11

12 Similarly, the PAO1/*p<sub>lac</sub>-YedQ* with increased biofilm formation could also dampen nematode  
13 motility and its ability to roam (Figure 1a-d, Supplementary Video 4), thus corroborating with  
14 the results from *wsp* operon. This showed that the biofilms could cause the quagmire  
15 phenotype for *C. elegans*.

16

17 *Psl is more important than Pel at impeding nematode locomotion under influence by wsp*  
18 *operon*

19 Since the *wsp* operon controls both Pel and Psl production [10], we next asked which  
20 exopolysaccharide played a larger role in the quagmire phenotype. To maximize the  
21 phenotypic effects of the EPS in question and ensure that our results were solely dependent on  
22 one EPS, we mutated the EPS genes in the  $\Delta wspF$  mutant. Presence of *wspF* mutation would  
23 boost the production of the exopolysaccharide whose synthesis genes were not mutated.

1 Hence, in this paper, unless specified otherwise, the Pel<sup>+</sup>Psl<sup>+</sup> referred to  $\Delta wspF$ ; Pel<sup>+</sup>Psl<sup>-</sup> was  
2  $\Delta wspF\Delta pslBCD$ ; Pel<sup>-</sup>Psl<sup>+</sup> was  $\Delta wspF\Delta pelA$ ; Pel<sup>-</sup>Psl<sup>-</sup> was  $\Delta wspF\Delta pelA\Delta pslBCD$ .

3

4 We found that the loss of Pel and Psl in Pel<sup>-</sup>Psl<sup>-</sup> completely abolished the quagmire  
5 phenotype, allowing the nematode to move at normal velocity and roam the bacterial lawn  
6 easily (Figure 2a-c, Supplementary Figure S4, Supplementary video 5). Surprisingly, loss of  
7 Pel in Pel<sup>-</sup>Psl<sup>+</sup> did not completely abolish the quagmire phenotype, while Psl loss in Pel<sup>+</sup>Psl<sup>-</sup>  
8 was comparable to Pel<sup>-</sup>Psl<sup>-</sup> (Figure 2a-c, Supplementary Figure S4, Supplementary Videos 6-  
9 7). While both exopolysaccharides were involved in the quagmire phenotype, Psl played a  
10 more important role in the quagmire phenotype as compared to Pel.

11

12 In the similar fashion, we inserted the *p<sub>lac</sub>-YedQ* plasmid into the EPS mutants and ultimately  
13 found that these results corroborated with our observations on the *wsp* operon (Supplementary  
14 Figure S5, Supplementary Videos 4, 8-10). Nevertheless, we ultimately found that our results  
15 were mainly dependent on the presence of the exopolysaccharide in the biofilm matrix, as we  
16 found qualitatively identical results when we used non-*wspF*-mutated backgrounds on PAO1,  
17  $\Delta pelA$ ,  $\Delta pslBCD$  and  $\Delta pelA\Delta pslBCD$  mutants (Supplementary Figure S6, Supplementary  
18 Videos 2, 11 – 13).

19

20 To confirm that the physical presence of the exopolysaccharide could contribute to the  
21 quagmire phenotype, we added Pel or Psl extracts exogenously to the Pel<sup>-</sup>Psl<sup>-</sup> strain at  
22 increasing concentrations. While increasing concentrations of Pel did not establish the  
23 quagmire phenotype in the Pel<sup>-</sup>Psl<sup>-</sup> (Figure 2e), we found that more than 1  $\mu\text{g ml}^{-1}$  Psl could

1 establish the quagmire phenotype, to the point of being similar to  $\Delta wspF$  (Figure 2f). This  
2 also corroborated with the levels of exopolysaccharide extracted from the biofilms  
3 (Supplementary Figure S2b). Hence, addition of physiologically-relevant Psl concentrations  
4 to the bacterial cells could alter the biofilm matrix and impede nematode motility.

#### 6 *Psl immobilizes and delays C. elegans from grazing susceptible biofilms*

7 Since *C. elegans* possesses chemotaxis behavior like most animals, where it moves in  
8 response either from repellents (such as noxious repellents and predators) or to attractants  
9 (such as prey, mate and odorants) [25], we next examined the implications of Psl-mediated  
10 interference on *C. elegans* motility.

11  
12 Using a modified repulsion assay [26], we designed an escape assay where we first placed *C.*  
13 *elegans* in the biofilm ‘trap’ and shone a direct beam of blue light on the biofilms (Figure 3a).  
14 Blue light was previously shown to be a noxious yet harmless repellent under brief exposure  
15 [26], so this would encourage *C. elegans* to leave the biofilm as soon as possible. By  
16 observing the average duration required by the nematodes to escape the biofilm ‘trap’ into the  
17 safe zone, we observed that the *C. elegans* took significantly longer time to escape from the  
18  $Pel^+Psl^+$  and  $Pel^-Psl^+$  mutants, with some of them even unable to escape from the biofilm  
19 ‘trap’ within ten minutes (Figure 3b). In contrast, it took lesser time for the animals to escape  
20 from the  $Pel^-Psl^-$  and  $Pel^+Psl^-$  biofilms (Figure 3b). This showed that Psl could not only  
21 impede *C. elegans* motility, it could effectively help the biofilm immobilize *C. elegans*.

22

1 We next asked what could be the possible benefit brought to the biofilms by immobilizing a  
2 predatory *C. elegans* within themselves. Since *C. elegans* is a predator which roamed around  
3 in search for food, we tested if Psl-producing biofilms could prevent or delay the roaming of  
4 *C. elegans*, so that the non-Psl producing biofilms or susceptible biofilms could be spared  
5 from nematode predation. Since our food preference assay had shown that *C. elegans* prefer  
6 *E. coli* OP50 over *P. aeruginosa* PAO1 (Supplementary Figure S7a), we designed an assay  
7 which set the *P. aeruginosa* biofilm as nematode ‘trap’ in the center of the petri dish, which  
8 was surrounded by the susceptible *E. coli* OP50 biofilm as ‘food bait’ to motivate the  
9 nematodes to leave the trap (Figure 3c). We then compared the extent of nematode tracks on  
10 the bait after their escape from the *P. aeruginosa* trap. Worms notably moved across a larger  
11 area of the bait over time after escaping quickly from the poorer trap (Pel<sup>-</sup>Psl<sup>-</sup> and Pel<sup>+</sup>Psl<sup>-</sup>  
12 mutants), whereas better traps (Pel<sup>+</sup>Psl<sup>+</sup> and Pel<sup>-</sup>Psl<sup>+</sup> mutants) could either reduce or  
13 completely prevent *C. elegans* from grazing on the bait, by delaying exit or immobilizing the  
14 nematodes (Figure 3d).

15  
16 This finding had significant implications on the recolonization ability of *C. elegans* on the  
17 susceptible OP50 lawns, where nearly 50% fewer L1 progenies (p<0.01) were observed  
18 growing on OP50 lawns after the adult nematodes had escaped from better traps (Pel<sup>+</sup>Psl<sup>+</sup> and  
19 Pel<sup>-</sup>Psl<sup>+</sup> mutants) and recolonized on susceptible OP50 lawns (Supplementary Figure S7b).  
20 Hence, Psl was comparatively more important than Pel in entrapping predators to delay or  
21 prevent susceptible biofilms from predation, thereby improving the overall survival of the  
22 biofilms.

23

1 *Role of other matrix components in the quagmire phenotype*

2 Other than Pel and Psl, the *P. aeruginosa* biofilm matrix comprises of a multitude of matrix  
3 components, each of which might play a role in dictating how *C. elegans* move across the  
4 biofilms. Since CdrA adhesion protein and eDNA were not significantly involved in the  
5 quagmire phenotype (Supplementary Figure S8), we tested alginate, the third and final  
6 exopolysaccharide in *P. aeruginosa*. Alginate production was controlled by the *muc* c-di-  
7 GMP signaling operon, and was responsible for mucoidy of a subset of clinical isolates in  
8 cystic fibrosis patients [27, 28]. Since its production was inversely regulated with Pel/Psl  
9 exopolysaccharides production, presence of Pel and Psl is minimal in mucoid strains [29]. We  
10 employed the  $\Delta mucA$  mutant ( $Alg^+$ ) whose mutation of *mucA* repressor causes the de-  
11 repression of MucR DGC, resulting in increased mucoid biofilm formation via the production  
12 of alginate (Supplementary Figure S1b). With higher exopolysaccharide concentration in  $Alg^+$   
13 strain than PAO1 wild-type (Supplementary Figure S2b), we showed that increased  
14 production of alginate could also impede *C. elegans* motility (Figure 4, Supplementary Video  
15 14). Mutagenesis of alginate synthesis gene *algT* in the  $\Delta mucA \Delta algT$  mutant ( $Alg^-$ ) resulted in  
16 abrogation of quagmire phenotype, allowing the *C. elegans* to roam the bacterial lawns freely  
17 at normal speed (Figure 4a-c, Supplementary Figure S9, Supplementary Video 15).  
18 Exogenous addition of alginate to the  $Alg^-$  mutant deficient in alginate production can restore  
19 the quagmire phenotype at  $1 \mu g ml^{-1}$  (Figure 4d). Similar to Psl, alginate could also  
20 immobilize *C. elegans* and prevent its escape from noxious blue light (Figure 4e). This  
21 implied that under the influence of *muc* operon, alginate was solely important to impeding  
22 nematode locomotion.

23

1 **Discussion:**

2 Bacteria are often the target of predation by bacterivores, such as nematodes and amoebae in the  
3 environment, and phagocytes in the human body. To ensure their survival, bacteria produce a  
4 plethora of virulence factors which can effectively kill their predators, such as phenazines,  
5 hydrogen cyanide and Type III secretion system (T3SS) [30-32]. Such virulence factors typically  
6 require hours to days to kill *C. elegans*, which are typically demonstrated in fast paralytic (8 to  
7 24 hrs) and slow killing assays (days to weeks) [33].

8  
9 Bacteria also form biofilms whose exopolymeric matrix offers protection to bacteria by resisting  
10 predation. To our knowledge, we showed a hitherto unreported function of the biofilm matrix,  
11 which was to impede nematode locomotion and alter its grazing ability. In the case of *P.*  
12 *aeruginosa*, Psl and alginate exopolysaccharides were important in entrapping and restricting  
13 nematode movement, thereby hampering *C. elegans*' ability to roam and forage for food. This  
14 observation was applicable to *C. elegans* of various ages and sizes tested, where young L1 larvae  
15 and adults had retarded motility on *P. aeruginosa* biofilms containing Psl or alginate, with  
16 increased propensity to be immobilized on the biofilm traps (Supplementary Figure S10).

17 Furthermore, this retarded motility was observed to be consistent for longer periods (up to 1 hr),  
18 implying the long-lasting effect of biofilms on nematode motility (Supplementary Figure S11).

19  
20 While Pel and Psl genes were commonly found in most environmental and clinical isolates,  
21 alginate was only expressed in a subset of mucoid clinical isolates [34], thus Psl could be  
22 prevalently employed by *P. aeruginosa* biofilms in nature as compared to alginate. Nevertheless,  
23 the redundancy of exopolysaccharides involved in the quagmire phenotype conferred versatility

1 in *P. aeruginosa* to respond to specific stimuli and adjust the composition of its biofilm matrix  
2 accordingly. This improved survival of *P. aeruginosa* biofilms in face of varying stresses and  
3 predators.

4  
5 While Pel is involved in scaffolding with eDNA-crossing-linking properties [35, 36], its  
6 viscosity allows bacterial cells to spread within the biofilm matrix, which may explain why the  
7 Pel exopolysaccharide was significantly less effective at impeding nematode locomotion than Psl  
8 [37].

9  
10 Yet for Psl, it is a rigid polymer which increases effective cross-linking of cells in the biofilm  
11 matrix, thus strengthening the scaffold and promoting the formation of stiff microcolonies [37].  
12 Without Psl, the biofilm matrix becomes less rigid [37], which may indicate why *C. elegans* can  
13 move across Psl-deficient biofilms easily. Nonetheless, further investigation of how these  
14 ‘sticky’ components interact with the proteinaceous outer cuticle of *C. elegans* is warranted.

15  
16 As for eDNA and CdrA adhesion protein, they do not have an observable effect on locomotion,  
17 which can be attributed to their lower presence in the matrix composition as compared to  
18 exopolysaccharides [38]. While biofilm matrix is directly involved in impeding nematode  
19 motility, upstream c-di-GMP-signaling proteins can indirectly influence the quagmire phenotype.  
20 Clearly, biofilms formed by DGC mutants ( $\Delta wspR$  and  $\Delta mucR$ ) are worse-off than wild-type  
21 PAO1 in retarding *C. elegans* locomotion (Supplementary figure S12), emphasizing their  
22 importance in the biofilms’ quagmire phenotype.

23

1 Our findings have several implications in nature and clinical settings. In the environment, the  
2 biofilms could impede the mobility of nematode as a form of protection from grazing and act as  
3 trap to reduce further damage to susceptible biofilms, thereby improving the overall survival of  
4 the biofilms. With diverse soil microbial species which are known to interact with nematodes  
5 [39], *C. elegans* remain susceptible to a variety of pathogens, such as *Leucobacter* and  
6 *Corynebacteria* species which could form robust biofilms that interact with *C. elegans* [40, 41].  
7 Furthermore, certain *Leucobacter* strains could form aggregates, which cause swimming worms to  
8 stick together by their tails in a dead-inducing entrapment (‘star formation’) [42]. This adds a  
9 layer of complexity in predator-prey interactions for future work on other bacterial species and  
10 bacterivores. Furthermore, our findings can be used as a gauge to test the physical parameters of  
11 various components in the biofilm matrix against predation.

12  
13 Our results also raised an interesting question into the prevalence of Pel and Psl synthesis genes  
14 possessed by different microbial species. A search of sequenced bacterial genomes from the *C.*  
15 *elegans* native microbiota [43, 44] for Pel and Psl synthesis genes using the IMG portal revealed  
16 that other *Pseudomonas* species, such as *Pseudomonas protegens* and *Pseudomonas lurida*, and  
17 non-*Pseudomonas* species such as *Delftia acidovorans* contained Pel genes (Supplementary Data  
18 S2). On the other hand, Psl genes were exclusively found in *Pseudomonas* species  
19 (Supplementary Data S2). This raised the possibility that *C. elegans* could encounter such  
20 biofilms in the soil.

21  
22 When we expanded the search to all sequenced microbial species, it was noted that more  
23 *Pseudomonas* species, such as *Pseudomonas protegens*, *Pseudomonas fluorescens* and

1 *Pseudomonas chlororaphis*, and non-*Pseudomonas* species such as *Burkholderia*,  
2 *Paraburkholderia* and *Pseudoalteromonas* contained Pel genes (Supplementary Figure S13a and  
3 Supplementary Data S3). Yet, Psl genes remained almost exclusive to *P. aeruginosa* and other  
4 *Pseudomonas* species (Supplementary Figure S13b and Supplementary Data S3). Such microbial  
5 species were isolated from a variety of locations, ranging from clinics to soil, plant roots and  
6 aquatic settings (Supplementary Data S3), indicating the prevalence of such biofilm  
7 exopolysaccharides in the environment where *C. elegans* could encounter. Furthermore, we  
8 observed addition of Psl or alginate to another species *E. coli* OP50 could also impede nematode  
9 motility and even reproduction rate of its predator (Supplementary Figure S14), raising the  
10 possibility that non-Psl producing microbial species could utilize Psl or inhabit with Psl-  
11 producing species for similar purposes.

12  
13 In clinical settings, clinical isolates such as mucoid strains with induced alginate expression and  
14 rough small colony variant (RSCV) strains with overexpression of Psl are frequently isolated  
15 from patients with cystic fibrosis, where phagocytosis of biofilm cells by immune cells was  
16 severely hampered [45, 46]. Our findings that the biofilm exopolysaccharides could impede  
17 predator motility raise the possibility that leukocytes have reduced migration and motility across  
18 the biofilms in human infections, thereby preventing biofilm clearance by the immune system.  
19 This warrants the need for development of anti-biofilm agents specific against biofilm matrix  
20 components [47].

2 **Figure 4.** Role of alginate in the quagmire phenotype. (a) Average velocity, (b) average  
 3 displacement and (c) representative tracks travelled by *C. elegans* ( $N \geq 150$ ) on PAO1, Alg<sup>+</sup>  
 4 and Alg<sup>-</sup> lawns. (d) Exogenous addition of alginate to Alg<sup>-</sup> strain. (e) Duration taken by *C.*  
 5 *elegans* to escape biofilm trap. Means and s.d. are shown. \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , n.s (not  
 6 significant), One-Way ANOVA.
